Subject: Initial Reference List, Draft Class 3 PMR

Hi George,

Attached is a list of reference documents in the DRAFT Class 3 PMR that NMED would like a copy of or a link to. Please let me know when you think these will be available. Thanks.

ANALYSES OF BACKFILLED TRANSURANIC WASTES DISPOSAL ROOMS

G. D. Callahan and K. L. DeVries
RE/SPEC Inc.
P.O. Box 725
Rapid City, SD 57709

ABSTRACT

The Waste Isolation Pilot Plant (WIPP) is a U.S. Department of Energy (DOE) research and development facility established to demonstrate the safe geologic disposal of transuranic (TRU) wastes generated from defense-related activities. Crushed salt and crushed-salt treatments are the candidate materials to be used as backfill around waste and waste packages in the underground disposal rooms. In response to room closure, the backfill is anticipated to compact sufficiently such that an effective seal is formed reducing brine inflow and radionuclide transport. In this report, different backfill and backfill/TRU waste combinations are investigated based on finite element simulations for a 200-year period conducted to examine and compare the sealing efficacy of different backfill scenarios. Specifically, disposal room content scenarios investigated include crushed salt, a crushed salt/bentonite mixture, crushed salt covering TRU waste, crushed salt/bentonite covering TRU waste, crushed salt covering a mixture of crushed salt and shredded metallic waste, and crushed salt covering vitrified waste. The simulations were conducted with the thermomechanical finite element program SPECTROM-32. The report includes a description of constitutive relations used to simulate the backfill and host rock formation including viscoplastic (creep), nonlinear elastic, creep consolidation, and nonlinear elastic and consolidation mixture models. The simulation results show that the backfill attains average void fractions less than 5 percent in all cases except for the case with crushed salt/bentonite covering TRU waste, which is only slightly greater than 5 percent. The time required to attain these void fractions varies considerably between cases.

The content of this report was effective as of April 1991. This report was prepared by RE/SPEC Inc. under Contract 40-2512 with Sandia National Laboratories.

ACKNOWLEDGMENTS

The authors are grateful to Barry M. Butcher and Frederick T. Mendenhall of Sandia National Laboratories for their review and constructive criticism of the report. The authors are appreciative and acknowledge the efforts of Joe L. Ratigan and Joel D. Nieland for their contributions in developing the TRU waste models used in this study.

1.0 INTRODUCTION

1.1 BACKGROUND

The U.S. Department of Energy is planning to dispose of transuranic wastes (TRU) at the Waste Isolation Pilot Plant (WIPP) near Carlsbad, New Mexico. The current mission of the WIPP is to provide a research and development facility to demonstrate the safe management, storage, and disposal of TRU wastes generated by U.S. Government defense programs. Sandia National Laboratories is conducting procedural and technical activities to assess compliance of the WIPP with regulatory requirements. Performance of seal, barrier, and backfill materials is being studied as part of these activities.

A key candidate component of the room backfill system is crushed salt. Crushed salt is an attractive candidate because it is readily available from the mining operations, it is compatible with the host rock, and it is expected to consolidate into a low-permeability mass comparable to the intact salt as a result of the creep closure of the surrounding rock mass. Crushed salt has been shown to consolidate relatively quickly when subjected to a hydrostatic stress [Holcomb and Hannum, 1982; Pfeifle and Senseny, 1985; Stroup and Senseny, 1987, and Holcomb and Zeuch, 1988]. Therefore, the backfill is expected to lower the effective permeability in the rooms and reduce the total time required for complete encapsulation of the waste. In addition, the backfill may be engineered so that it actually adsorbs radionuclides and thus, provides an additional barrier around the waste. Crushed salt and varying amounts of bentonite, a montmorillonite-rich clay, have been proposed as candidate backfill materials that improve the properties of pure crushed salt. The addition of bentonite reduces permeability and increases the absorbing ability of the mixture. However, the addition of bentonite may have its drawbacks. Preliminary results from consolidation tests suggest that the rate of consolidation for crushed salt/bentonite backfills is less than that for pure crushed salt [Pfeifle, 1990; Stroup and Senseny, 1987]. This result implies that the time required for complete encapsulation of the waste is longer for the crushed salt/bentonite backfills. Another disadvantage of bentonite is that it swells in the presence of water or brine [Pusch, 1980]. In a storage room where the backfill is confined, a swelling pressure may develop. This swelling pressure may be large and could add significantly to the time required for complete encapsulation of the waste since the natural tendency of the intact rock to deform into the room is decreased.

Because of the importance of backfills at WIPP, knowledge of their constitutive behavior and the ability to perform long-term structural analyses of backfill schemes are required. Clearly, an understanding of the mechanical behavior of crushed salt is important at WIPP. Optimization of the backfill emplacement is necessary to promote room stability, to enable sufficient backfill consolidation to reduce brine

flow which retards the transport of soluble radionuclides, and to maintain sufficient gas permeability to avoid gas pressurization [Butcher, 1990].

1.2 SCOPE

The study presented in this report was conducted to investigate the consolidation of backfill and waste in disposal room configurations at the WIPP. Six cases were investigated that included the following assumed room contents:

1. Completely filled with crushed salt.
2. Completely filled with a 70 percent crushed salt — 30 percent bentonite (by weight) mixture.
3. TRU waste covered with crushed salt.
4. TRU waste covered with a 70 percent crushed salt — 30 percent bentonite (by weight) mixture.
5. An 80 percent crushed salt — 20 percent shredded metallic waste (by volume) mixture covered with crushed salt.
6. Vitrified waste covered by crushed salt.

To solve these six problems, representative constitutive relations were developed and implemented for the crushed salt and TRU waste. Numerical simulations of the backfill, waste, and creeping host bedded salt formation were conducted for 200 years. The finite element program, SPECTROM-32 [Callahan et al., 1990], was used to perform the analyses.

1.3 REPORT ORGANIZATION

This report includes six chapters and three appendixes. Chapter 2 describes the constitutive relations and material parameters used to describe the backfill materials, waste materials, and the host rock formation. Chapter 3 describes the finite element idealization of the disposal room configuration and procedures used to conduct the analyses. The results of the analyses are given in Chapter 4, and Chapter 5 provides the conclusions of the study. References cited in the report are given in Chapter 6. Appendix A includes stress-porosity data from simulated TRU waste compaction experiments. Appendix B contains a comparison of results obtained with the finite element program SANCHO [Weatherby and Brown, 1990 and Weatherby, 1989] to the comparable analyses described here. Appendix C contains average void fraction and mean stress results from the analyses.

2.0 CONSTITUTIVE RELATIONS AND MATERIAL PROPERTIES

This chapter presents the constitutive relationships or models used to represent the various materials associated with the analysis of TRU waste disposal rooms. The models presented are for the natural or intact rock salt, crushed salt, crushed salt mixed with other materials, and TRU waste. Each of these material models are discussed separately in the following subsections. Because temperature variations within the repository are assumed to be small, the thermal strains are neglected in each of the discussions; however, the thermal strain rates may be included as a component of the total strain rate in each of the models as reported previously [Callahan et al., 1990].

2.1 INTACT SALT

The total strain rate for the natural rock salt or intact salt constitutive model is assumed to include two components. The components consist of elastic and creep contributions, and the total strain rate is written as

$$\dot{\epsilon}_{ij} = \dot{\epsilon}^e_{ij} + \dot{\epsilon}^c_{ij} \tag{2-1}$$

The elastic strains (ϵ^e_{ij}) are assumed to be linear elastic and given by Hooke's Law (e.g., Timoshenko and Goodier [1970]). The creep strains (ϵ^c_{ij}) are described by Munson et al. [1989]. Summaries of the linear elastic and creep portions of the model are given here for completeness.

2.1.1 Linear Elastic Model

The elastic strains, ϵ^e_{ij}, are the contribution from the stress field given by Hooke's law

$$\epsilon^e_{ij} = C_{ijkl}\sigma_{kl} \tag{2-2}$$

where C_{ijkl} is the matrix of elastic constants and σ_{kl} is the stress tensor.

For an isotropic body, there are two independent elastic constants and Equation 2-2 can be written as

$$\epsilon^e_{ij} = \frac{1}{E}\left[(1+\nu)\,\sigma_{ij} - \nu\sigma_{kk}\delta_{ij}\right] \tag{2-3}$$

where the elastic material constants E and ν represent Young's modulus and Poisson's ratio. We may also write Equation 2-3 in terms of the bulk modulus (K) and shear modulus (G) for the material as

$$\epsilon^e_{ij} = \frac{\sigma_m}{3K}\,\delta_{ij} + \frac{S_{ij}}{2G} \tag{2-4}$$

where

$$\begin{aligned} \sigma_m &= \frac{\sigma_{kk}}{3}, \text{ mean stress} \\ S_{ij} &= \sigma_{ij} - \sigma_m \delta_{ij}, \text{ deviatoric stress} \\ \delta_{ij} &= \text{Kronecker delta.} \end{aligned} \tag{2-5}$$

Equation 2-3 may be rearranged to give the elastic constitutive equations for stress in terms of strain

$$\sigma_{ij} = \frac{E}{(1+\nu)(1-2\nu)} \left[(1-2\nu)\, \epsilon^e_{ij} + \nu \epsilon^e_{kk} \delta_{ij} \right] \tag{2-6}$$

2.1.2 Creep Model

For the inelastic creep strains, the modified Munson-Dawson material model [Munson et al., 1989] is used. The model is written as

$$\dot{\epsilon}^c_e = F \dot{\epsilon}_s \tag{2-7}$$

where $\dot{\epsilon}^c_e$ is the invariant inelastic strain-rate measure, and $\dot{\epsilon}_s$ is the steady-state strain rate. The transient function F consists of three branches — a workhardening branch, an equilibrium branch, and a recovery branch and is written in that order as

$$F = \begin{cases} \exp\left[\Delta \left(1 - \frac{\varsigma}{\epsilon^f_t}\right)^2\right] & \varsigma < \epsilon^f_t \\ 1 & \varsigma = \epsilon^f_t \\ \exp\left[-\delta \left(1 - \frac{\varsigma}{\epsilon^f_t}\right)^2\right] & \varsigma > \epsilon^f_t \end{cases} \tag{2-8}$$

Δ and δ are the workhardening and recovery parameters, respectively, and ϵ^f_t is the transient strain-rate limit. The internal variable ς is governed by the evolutionary equation

$$\dot{\varsigma} = (F-1)\, \dot{\epsilon}_s \tag{2-9}$$

and the transient strain-rate limit is given by

$$\epsilon^f_t = K_o e^{cT} \left(\frac{\sigma_e}{\mu}\right)^m \tag{2-10}$$

where K_o, c, m, and μ are material parameters, T is temperature, and σ_e is an invariant stress measure described later.

The workhardening parameter is defined as a function of stress

$$\Delta = \alpha + \beta \log\left(\frac{\sigma_e}{\mu}\right) \tag{2-11}$$

where α and β are material parameters. Because of insufficient laboratory data to allow evaluation, the recovery parameter δ is taken to be a constant.

The steady-state strain rate is the sum of the three individual strain-rate mechanisms acting in parallel

$$\dot{\epsilon}_s = \sum_{i=1}^{3} \dot{\epsilon}_{s_i} \tag{2-12}$$

The three contributing mechanisms — dislocation climb, an undefined mechanism, and glide are written respectively as

$$\dot{\epsilon}_{s_1} = A_1 \left(\frac{\sigma_e}{\mu}\right)^{n_1} \exp\left(-\frac{Q_1}{RT}\right) \tag{2-13}$$

$$\dot{\epsilon}_{s_2} = A_2 \left(\frac{\sigma_e}{\mu}\right)^{n_2} \exp\left(-\frac{Q_2}{RT}\right) \tag{2-14}$$

$$\dot{\epsilon}_{s_3} = \left(\hat{B}_1 e^{-Q_1/RT} + B_2 e^{-Q_2/RT}\right) \sinh\left[q\left(\frac{\sigma_e - \sigma_0}{\mu}\right)\right] H\left(\sigma_e - \sigma_0\right) \tag{2-15}$$

where

μ = normalizing parameter (MPa)

q = activation volume

$A_1,\ A_2,\ \hat{B}_1,\ B_2,\ n_1,\ n_2,$
$Q_1,\ Q_2,\ \sigma_0,\ K,\ m,\ \alpha,\ \beta,\ \delta$ = experimental constants (see Table 2-1)

R = 1.987, universal gas constant $(\frac{\text{cal}}{\text{mol-K}})$

$H(.)$ = Heaviside step function.

To generalize the Munson-Dawson model to three-dimensional states of stress, Fossum et al. [1988] is followed to determine flow potential functions generalized according to Mises and Tresca types of flow potential functions. The inelastic tensorial strain-rate components may be written as

$$\dot{\epsilon}^c_{ij} = \dot{\epsilon}^c_e \frac{\partial \sigma^f_e}{\partial \sigma_{ij}} \tag{2-16}$$

where the invariant inelastic strain-rate measure is

$$\dot{\epsilon}^c_e = \dot{\epsilon}^c_e\left(T,\ \sigma_e,\ \epsilon^c_e\right) \tag{2-17}$$

The two invariant stress measures in Equations 2-16 and 2-17 are given by

$$\begin{aligned} \sigma_e^f &= \sigma_e^f(\sigma_m,\ J_2,\ J_3) \\ \sigma_e &= \sigma_e(\sigma_m,\ J_2,\ J_3) \end{aligned} \tag{2-18}$$

where the mean stress (σ_m), the second invariant of the deviator stress (J_2), and the third invariant of the deviator stress (J_3) are given by

$$\begin{aligned} \sigma_m &= \frac{\sigma_{kk}}{3} \\ J_2 &= \tfrac{1}{2} S_{ij} S_{ji} \\ J_3 &= \tfrac{1}{3} S_{ij} S_{jk} S_{ki} \end{aligned} \tag{2-19}$$

The Lode angle (ψ), which is a convenient alternative to J_3, is given by

$$\psi = \tfrac{1}{3} \sin^{-1}\left[\frac{-3\sqrt{3} J_3}{2 J_2^{3/2}}\right], \quad \left(-\frac{\pi}{6} \le \psi \le \frac{\pi}{6}\right) \tag{2-20}$$

The partial derivative given in Equation 2-16 may be determined using the chain rule as

$$\frac{\partial \sigma_e^f}{\partial \sigma_{ij}} = \frac{\partial \sigma_e^f}{\partial \sigma_m}\frac{\partial \sigma_m}{\partial \sigma_{ij}} + \frac{\partial \sigma_e^f}{\partial J_2}\frac{\partial J_2}{\partial \sigma_{ij}} + \frac{\partial \sigma_e^f}{\partial \psi}\frac{\partial \psi}{\partial J_3}\frac{\partial J_3}{\partial \sigma_{ij}} \tag{2-21}$$

The derivatives of the invariants in Equation 2-21 are the same regardless of the invariant stress and strain measures selected. These derivatives [Callahan, 1982] are

$$\begin{aligned} \frac{\partial \sigma_m}{\partial \sigma_{ij}} &= \frac{\delta_{ij}}{3} \\ \frac{\partial J_2}{\partial \sigma_{ij}} &= S_{ij} \\ \frac{\partial \psi}{\partial J_3}\frac{\partial J_3}{\partial \sigma_{ij}} &= -\frac{\sqrt{3}}{2 J_2^{3/2} \cos 3\psi}\, t_{ij} \end{aligned} \tag{2-22}$$

where

$$t_{ij} = S_{ip} S_{pj} - \tfrac{2}{3} J_2 \delta_{ij}$$

Therefore, to define completely the inelastic strain-rate measure required by Equation 2-17, the invariant stress and strain-rate measures need to be prescribed. The equivalent inelastic strain-rate measure is given by the Munson-Dawson material model in Equation 2-7. Two types of invariant stress measures are considered.

These are termed the pressure-dependent and frictional forms of the invariant stress measure. The pressure-dependent form is similar to the Mises-Schleicher plastic potential, and the frictional form is similar to the Mohr-Coulomb plastic potential. Mathematically, these stress measures are

$$\sigma_e^f = 3\tau\sigma_m + \sqrt{3J_2} \quad \text{(pressure-dependent)} \tag{2-23}$$

$$\sigma_e^f = 2\sin\tau\sigma_m + \left(\cos\psi - \frac{\sin\psi\sin\tau}{\sqrt{3}}\right) 2\sqrt{J_2} \quad \text{(frictional)} \tag{2-24}$$

The variable τ is a material constant termed the flow dilatancy parameter. The other invariant stress measure (σ_e) that needs to be described is taken to be identical to those given in Equations 2-23 and 2-24, except that the parameter τ is replaced by a different variable (θ), viz

$$\sigma_e = 3\theta\sigma_m + \sqrt{3J_2} \tag{2-25}$$

$$\sigma_e = 2\sin\theta\sigma_m + \left(\cos\psi - \frac{\sin\psi\sin\theta}{\sqrt{3}}\right) 2\sqrt{J_2} \tag{2-26}$$

The variable θ is a material constant termed the frictional parameter. If $\theta = \tau$, then $\sigma_e = \sigma_e^f$; however, this is not required theoretically.

Equation 2-21 requires the partial derivatives of the invariant stress measures with respect to stress. Differentiation of Equations 2-23 and 2-24 provides these quantities for the pressure-dependent and frictional forms for the invariant stress measures. These quantities are as follows:

Pressure-Dependent

$$\begin{aligned} \frac{\partial\sigma_e^f}{\partial\sigma_m} &= 3\tau \\ \frac{\partial\sigma_e^f}{\partial J_2} &= \frac{\sqrt{3}}{2\sqrt{J_2}} \\ \frac{\partial\sigma_e^f}{\partial\psi} &= 0 \end{aligned} \tag{2-27}$$

Frictional

$$\begin{aligned}
\frac{\partial \sigma_e^f}{\partial \sigma_m} &= 2\sin\tau \\
\frac{\partial \sigma_e^f}{\partial J_2} &= \left[\frac{\cos 2\psi}{\cos 3\psi} + \frac{\sin\tau}{\sqrt{3}}(\tan 3\psi \cos\psi - \sin\psi)\right]\frac{1}{\sqrt{J_2}} \\
\frac{\partial \sigma_e^f}{\partial \psi} &= -\left[\sin\psi + \frac{\cos\psi \sin\tau}{\sqrt{3}}\right] 2\sqrt{J_2}
\end{aligned} \tag{2-28}$$

By letting τ go to zero in Equations 2-23 and 2-24, we eliminate the mean-stress dependence and obtain Mises- and Tresca-types of invariant stress measures, respectively. θ is also set to zero such that $\sigma_e = \sigma_e^f$. Thus, Equations 2-23 and 2-24 become

$$\sigma_e = \sqrt{3J_2} \quad \text{(Mises)} \tag{2-29}$$

$$\sigma_e = 2\cos\psi\sqrt{J_2} \quad \text{(Tresca)} \tag{2-30}$$

and the derivatives in Equations 2-27 and 2-28 become

Mises

$$\begin{aligned}
\frac{\partial \sigma_e}{\partial \sigma_m} &= 0 \\
\frac{\partial \sigma_e}{\partial J_2} &= \frac{\sqrt{3}}{2\sqrt{J_2}} \\
\frac{\partial \sigma_e}{\partial \psi} &= 0
\end{aligned} \tag{2-31}$$

Tresca

$$\begin{aligned}
\frac{\partial \sigma_e}{\partial \sigma_m} &= 0 \\
\frac{\partial \sigma_e}{\partial J_2} &= \left[\frac{\cos 2\psi}{\cos 3\psi}\right]\frac{1}{\sqrt{J_2}} \\
\frac{\partial \sigma_e}{\partial \psi} &= -2\sin\psi\sqrt{J_2}
\end{aligned} \tag{2-32}$$

Substituting Equations 2-31, 2-22, and 2-21 into Equation 2-16 gives the familiar generalization for the Mises flow potential

$$\dot{\epsilon}^c_{ij} = \frac{3\dot{\epsilon}^c_e}{2\sqrt{3J_2}} S_{ij} \tag{2-33}$$

and substituting Equations 2-32, 2-22, and 2-21 into Equation 2-16 gives the generalization for the Tresca flow potential

$$\dot{\epsilon}^c_{ij} = \dot{\epsilon}^c_e \left\{ \left[\frac{\cos 2\psi}{\cos 3\psi} \right] \frac{S_{ij}}{\sqrt{J_2}} + \left[\frac{\sqrt{3} \sin \psi}{J_2 \cos 3\psi} \right] t_{ij} \right\} \tag{2-34}$$

Finally, substitution of Equation 2-7 into Equations 2-33 and 2-34 gives the generalization of the Munson-Dawson model for Mises (octahedral shear) and Tresca (maximum shear) types of flow potentials, respectively. The Tresca flow generalization was used in the analyses reported here.

Equation 2-34 is seen to be indeterminant as the Lode angle approaches ± 30. In other words, the flow potential forms corners at $\psi = \pm 30$ and the direction of straining is not unique. To eliminate this problem computationally, Equation 2-34 is evaluated in the limit as $\psi \rightarrow \pm 30$. Performing this limiting operation, Equation 2-34 becomes

$$\lim_{\psi \rightarrow \pm 30} \left(\dot{\epsilon}^c_{ij} \right) = \dot{\epsilon}^c_e \left\{ \frac{S_{ij}}{\sqrt{3J_2}} \mp \frac{t_{ij}}{2J_2} \right\} \tag{2-35}$$

In SPECTROM-32, Equation 2-35 is used when the Lode angle is within 0.25 degrees of $\pm 30°$.

2.1.3 Material Properties for Intact Salt

The linear elastic parameter values for the constitutive relation given in Equation 2-3 and the parameter values for the Munson-Dawson constitutive equation given in Equation 2-7 are presented in Table 2-1. Density of the intact salt is 2,140 kg/m^3. The intact salt material parameters were taken from Munson [1989] for pure halite.

2.2 CRUSHED SALT

The total strain rate for the crushed salt constitutive model is assumed to consist of two components. The components are nonlinear elastic and creep consolidation contributions and the total strain rate is written as

$$\dot{\epsilon}_{ij} = \dot{\epsilon}^e_{ij} + \dot{\epsilon}^c_{ij} \tag{2-36}$$

Table 2-1. Material Parameter Values for Intact Salt[a]

Parameter	Units	Value
Elastic Parameter Values

(a) Munson [1989] for pure halite.

The nonlinear elastic, ϵ_{ij}^e, and creep consolidation strains, ϵ_{ij}^c, are described by Callahan [1990] but are included here for completeness. Both the nonlinear elastic and creep consolidation portions of the model describe the material behavior in bulk (volumetric) and in shear (deviatoric). Although other models exist and are under consideration to describe the behavior of crushed salt (e.g., Zeuch [1989]), the nonlinear elastic and creep consolidation models for crushed salt were adapted from those given by Sjaardema and Krieg [1987].

2.2.1 Nonlinear Elastic Model for Crushed Salt

The elastic model described in Section 2.1.1 is applicable to the crushed salt with the following described procedure used to incorporate the nonlinearity in a piecewise manner.

For the nonlinear elastic model, the functional forms for the elastic constants given by Sjaardema and Krieg [1987] are adopted. They propose bulk and shear moduli as exponential functions of the current density, ρ_s. Tensile stresses and extensile strains are assumed to be positive. Functional forms of the elastic constants are written in terms of the total volumetric strain, ϵ_v ($\epsilon_v = \epsilon_{kk} = \epsilon_{11} + \epsilon_{22} + \epsilon_{33}$), using the relation

$$\rho_s = \frac{\rho_0^s}{1 + \epsilon_v} \tag{2-37}$$

where ρ_0^s is the initial or original density of the material. The bulk modulus and shear modulus (K_s and G_s) are given by

$$\begin{aligned} K_s &= K_0 e^{\frac{K_1 \rho_0}{1+\epsilon_v}} \\ G_s &= G_0 e^{\frac{G_1 \rho_0}{1+\epsilon_v}} \end{aligned} \tag{2-38}$$

where K_0, K_1, G_0, and G_1 are material constants.

At any time, the current values of Young's modulus and Poisson's ratio are computed from the current values of bulk and shear modulus using the relations

$$\begin{aligned} E &= \frac{9 K_s G_s}{3 K_s + G_s} \\ \nu &= \frac{3 K_s - 2 G_s}{6 K_s + 2 G_s} \end{aligned} \tag{2-39}$$

Equations 2-39 are used in Equation 2-3 to compute the elastic strains.

To solve the nonlinear elastic problem, the method of load incrementation is used to approximate the tangent modulus. The following set of simultaneous equations has to be solved in the direct stiffness finite element approach

$$[K_t]\{u\} + \{f\} = 0 \tag{2-40}$$

where f is the total load (or unload) vector, u is the displacement, and the tangent stiffness matrix K_t is a function of displacement (strain).

$$K_t = K_t(u) \tag{2-41}$$

The load vector is divided into a number of small increments Δf such that the series of tangent moduli will approximate a given stress-strain curve. K_t is first approximated assuming $\epsilon_v = 0$, or we are assuming that $\Delta u^0 = 0$ and

$$\left[K_t^0\right]\{\Delta u^1\} + \{\Delta f^1\} = 0 \tag{2-42}$$

Repetition of this process for each of the load increments may be written as

$$\{\Delta u^n\} = -\left[K_t^{n-1}\right]^{-1}\{\Delta f^n\} \tag{2-43}$$

The process is continued for each of the load increments, and the displacement is accumulated, i.e.,

$$\{u\} = \{u\} + \{\Delta \delta^n\} \tag{2-44}$$

Clearly, the functional forms adopted for bulk and shear moduli (Equations 2-38) allow increase without bound. Therefore, maximum values for bulk modulus K_f and shear modulus G_f are introduced based on the fully consolidated or intact values for the material. If either the intact bulk or shear modulus values are reached, the tangent modulus is no longer allowed to change, and the material is assumed to be intact with a constant stiffness.

2.2.2 Creep Consolidation Model for Crushed Salt

To develop the creep consolidation constitutive equation, general considerations are first observed and then specific functional forms are guided by available laboratory data. From the application of thermodynamic concepts, the three-dimensional generalization for creep strain rates is given by Fossum et al. [1988]. Following this approach, two continuum internal variables are assumed, the average inelastic volumetric strain, $\epsilon^c_{eq_1}$, and the average equivalent inelastic shear strain, $\epsilon^c_{eq_2}$.

$$\dot{\epsilon}^c_{ij} = \dot{\epsilon}^c_{eq_1}\frac{\partial \sigma^f_{eq_1}}{\partial \sigma_{ij}} + \dot{\epsilon}^c_{eq_2}\frac{\partial \sigma^f_{eq_2}}{\partial \sigma_{ij}} \tag{2-45}$$

For the first portion (volumetric) of Equation 2-45, the invariant strain-rate measure is

$$\dot{\epsilon}^c_{eq_1} = \dot{\epsilon}_v(\sigma_m) \tag{2-46}$$

The volumetric strain rate $\dot{\epsilon}^c_v$ is described empirically by Sjaardema and Krieg [1987] based on hydrostatic laboratory test data on crushed salt as

$$\dot{\epsilon}^c_v = \frac{(1+\epsilon_v)^2}{\rho_0} B_0\left[1 - e^{-B_1\sigma_m}\right] e^{\frac{A\rho_0}{1+\epsilon_v}} \tag{2-47}$$

where

$$\begin{aligned} \epsilon_v &= \epsilon_{kk}, \text{ total volumetric strain} \\ \epsilon_v^c &= \epsilon_{kk}^c, \text{ volumetric creep strain} \\ \sigma_m &= \frac{\sigma_{kk}}{3}, \text{ mean stress} \\ \rho_0^s &= \text{initial density} \\ B_0,\, B_1,\, A &= \text{material constants (see Table 2-3).} \end{aligned}$$

The invariant stress measure is given by

$$\sigma_{eq_1}^f = \sigma_m \tag{2-48}$$

For the second portion (deviatoric) of Equation 2-45, the invariant strain-rate measure is taken to be

$$\dot{\epsilon}_{eq_2}^c = \eta \dot{\epsilon}_{eq_1}^c = \eta \dot{\epsilon}_v \left(\sigma_m\right) \tag{2-49}$$

and the invariant stress is assumed to be a scalar multiple of the octahedral shear stress

$$\sigma_{eq_2}^f = \sigma_e = \sqrt{3J_2} \tag{2-50}$$

where J_2 is the second invariant of the stress deviator ($J_2 = \frac{1}{2} S_{ij} S_{ij}$). Substituting into Equation 2-45 and performing the required differentiation gives

$$\dot{\epsilon}_{ij}^c = \dot{\epsilon}_v^c \frac{\delta_{ij}}{3} + \eta \dot{\epsilon}_v^c \frac{3 S_{ij}}{2\sigma_e} \tag{2-51}$$

η is selected such that in a uniaxial test, the lateral components of $\dot{\epsilon}_{ij}^c$ equal zero. This requires that $\eta = -\frac{2}{3}$. Simple example problems that illustrate the creep consolidation behavior with and without the deviatoric component are given by Callahan [1990]. After substituting for $\dot{\epsilon}_v^c$ in Equation 2-51, the strain rate components are given by

$$\dot{\epsilon}_{ij}^c = \frac{\left(1+\epsilon_v\right)^2}{\rho_0} B_0 \left[1 - e^{-B_1 \sigma_m}\right] e^{\frac{A\rho_0}{1+\epsilon_v}} \left\{ \frac{\delta_{ij}}{3} - \frac{S_{ij}}{\sigma_e} \right\} \tag{2-52}$$

Obviously, the creep consolidation equation will allow unlimited consolidation. Therefore, a cap is introduced that eliminates further consolidation when the intact material density ρ_f is reached. Thus, when the condition

$$|\epsilon_v| \geq \left| \frac{\rho_0}{\rho_f} - 1 \right| \tag{2-53}$$

is satisfied, no further creep consolidation occurs. In addition, the creep consolidation is not permitted to generate tensile stresses. The procedure used to eliminate any tensile stresses is the same as described by Callahan et al. [1990]. An option is included that allows a consolidating material's constitutive model to be redefined following complete consolidation. For example, a crushed salt material can be prescribed to behave according to the intact salt constitutive relation given in Equation 2-34 following complete consolidation.

2.2.3 Combined Crushed Salt Model

The final equation for the total strain in the constitutive model for crushed salt (neglecting thermal strains) is obtained by substituting Equations 2-4 and 2-52 into Equation 2-36

$$\dot{\epsilon}_{ij} = \frac{\dot{\sigma}_m}{3K}\delta_{ij} + \frac{\dot{S}_{ij}}{2G} + \frac{(1+\epsilon_v)^2}{\rho_0} B_0 \left[1 - e^{-B_1\sigma_m}\right] e^{\frac{A\rho_0}{1+\epsilon_v}} \left\{\frac{\delta_{ij}}{3} - \frac{S_{ij}}{\sigma_e}\right\} \tag{2-54}$$

The above equation may be collapsed to yield the total volumetric strain-rate ($\dot{\epsilon}_v$) expression for the model. Performing this operation yields

$$\dot{\epsilon}_v = \frac{\dot{\sigma}_m}{K} + \frac{(1+\epsilon_v)^2}{\rho_0} B_0 \left[1 - e^{-B_1\sigma_m}\right] e^{\frac{A\rho_0}{1+\epsilon_v}} \tag{2-55}$$

When the combined nonlinear elastic and creep consolidation model is used, the relative change in the Euclidean or L_2 norm of the volumetric strain is monitored over time and the stiffness is updated when the change is greater than a user prescribed tolerance. Further details may be found in Callahan [1990].

2.2.4 Material Properties for Crushed Salt

The nonlinear elastic parameter values describing the nonlinear moduli for crushed salt defined in Equation 2-38 are given in Table 2-2. Table 2-2 also gives the assumed initial and final (intact) densities for the crushed salt used in this study. Engineering of the backfill could change the initial density substantially. Table 2-3 presents the parameter values for the creep consolidation constitutive equation given in Equation 2-52. The crushed salt material parameters are taken from Sjaardema and Krieg [1987].

Table 2-2. Nonlinear Elastic Material Parameters for Crushed Salt

Parameter	Units	Value
K_0	MPa	0.01760[a]
K_1	m^3/kg	0.00653[a]
G_0	MPa	0.01060[a]
G_1	m^3/kg	0.00653[a]
K_f	MPa	20,626[b]
G_f	MPa	12,423[b]
ρ_0^s	kg/m^3	1,400[c]
ρ_f	kg/m^3	2,140[a]

(*a*) Sjaardema and Krieg [1987].

(*b*) Computed using Equation 2-38 at ρ_f.

(*c*) Weatherby [1989].

Table 2-3. Creep Consolidation Material Parameters for Crushed Salt

Parameter	Units	Value[a]
B_0	$kg/m^3 \cdot s^{-1}$ $kg/m^3 \cdot yr^{-1}$	$1.3 \times 10^{+8}$ $4.10 \times 10^{+15}$

2.3 CRUSHED SALT MIXTURES

For the TRU waste disposal rooms, two crushed salt mixtures are of current interest: (1) crushed salt mixed with bentonite and (2) crushed salt mixed with TRU waste.

2.3.1 Crushed Salt/Bentonite Mixture Model

The functional form of the constitutive model selected to represent crushed salt/bentonite mixtures is identical to the crushed salt model since testing completed to date is inadequate to formulate a new constitutive model for crushed salt/bentonite mixtures. Therefore, Equation 2-52 applies to crushed salt/bentonite using material parameter values specific to the crushed salt/bentonite mixture given in Section 2.3.3.1.

2.3.2 Crushed Salt/TRU Waste Mixture Model

A possible waste treatment consists of simply mixing TRU waste with crushed salt and allowing the crushed salt to encapsulate the waste as the disposal room closes and the crushed salt consolidates. To develop constitutive relations for these types of mixtures, it is assumed that the TRU waste component consists of shredded metal wastes, is linear elastic, and is effectively an inert noninteracting material. Therefore, Equations 2-3 and 2-4 apply to the inert mixture material. Mixture theory is used to combine the crushed salt constitutive relations (nonlinear elasticity and creep consolidation) with the TRU waste.

2.3.2.1 Creep Consolidation Response of TRU Waste and Crushed Salt Mixtures

The creep consolidation model for a consolidating material mixed with another inert material is developed in this section. The creep consolidation relation for crushed salt is developed in Section 2.2.2 with the volumetric creep strain rate for crushed salt consolidation given in Equation 2-47. To distinguish the volumetric strain of the crushed salt from that of the mixture, the following definitions are used in the development:

$$\begin{aligned} \epsilon_{vs} &= \text{total volumetric strain of crushed salt} \\ \epsilon_v &= \text{total volumetric strain of the mixture.} \end{aligned}$$

The total volume of the mixture (V) is

$$V = V_s + V_m \tag{2-56}$$

where

$$\begin{aligned} V_s &= \text{volume of crushed salt} \\ V_m &= \text{volume of inert material.} \end{aligned}$$

Equation 2-56 may also be written as

$$V = \frac{m_s M}{\rho_s} + \frac{m_m M}{\rho_m} \tag{2-57}$$

where

$$\begin{aligned} m_s &= \text{mass fraction of salt} \\ m_m &= \text{mass fraction of inert material} \\ \rho_s &= \text{current density of the crushed salt} \\ M &= \text{total mass of the mixture.} \end{aligned}$$

Dividing Equation 2-57 by the total mass gives

$$\frac{1}{\rho} = \frac{m_s}{\rho_s} + \frac{m_m}{\rho_m} \tag{2-58}$$

where ρ is the current density of the mixture. If the density of the mixture is known, the density of the crushed salt can be found from Equation 2-58 as

$$\rho_s = \frac{\rho \rho_m m_s}{\rho_m - \rho m_m} \tag{2-59}$$

The initial density of the mixture ρ_0 can be found by substituting the initial crushed salt density into Equation 2-58

$$\rho_0 = \frac{\rho_0^s \rho_m}{m_s \rho_m + m_m \rho_0^s} \tag{2-60}$$

The rate of change of the density of the mixture is given by differentiating Equation 2-58 with respect to time. The volumetric strain of the inert material is assumed to be small such that the density of the inert material is constant. Performing the differentiation yields

$$\dot{\rho} = \frac{m_s \rho^2}{\rho_s^2} \dot{\rho}_s \tag{2-61}$$

If the relationships between the density and volumetric strain, i.e.,

$$\rho = \frac{\rho_0}{1 + \epsilon_v} \tag{2-62}$$

$$\rho_s = \frac{\rho_0^s}{1 + \epsilon_{vs}} \tag{2-63}$$

are substituted into Equation 2-61, the volumetric strain rate for the mixture is determined as

$$\dot{\epsilon}_v = \frac{m_s \rho_0}{\rho_0^s} \dot{\epsilon}_{vs} \tag{2-64}$$

The current density of the crushed salt may be expressed as

$$\rho_s = \frac{M_s}{V_s} = \frac{m_s M}{v_s V} = \frac{m_s \rho}{v_s} \tag{2-65}$$

where M_s is the mass of the salt. Thus, the volume fraction of the crushed salt v_s is

$$v_s = \frac{m_s \rho}{\rho_s} \tag{2-66}$$

The initial volume fraction of crushed salt is obtained by substituting the initial densities into Equation 2-66

$$v_0^s = \frac{m_s \rho_0}{\rho_0^s} \tag{2-67}$$

Substituting Equation 2-67 into Equation 2-64 yields

$$\dot{\epsilon}_v = v_0^s \dot{\epsilon}_{vs} \tag{2-68}$$

Thus, Equation 2-68 describes the volumetric strain rate of crushed salt mixed with an inert material in terms of the volumetric strain rate of the crushed salt. Assuming that the volumetric strain rate is the sum of the elastic and creep portions, Equation 2-68 may be written as

$$\dot{\epsilon}_v^c + \dot{\epsilon}_v^e = v_0^s \left(\dot{\epsilon}_{vs}^c + \dot{\epsilon}_{vs}^e \right) \tag{2-69}$$

The elastic strain rates are assumed to be negligible compared to the creep consolidation strain rates. To evaluate the relative magnitudes of the strain rates, conditions applicable to analyses relevant to our situation will be considered. Based on an initial density of 1,400 kg/m^3, the initial bulk modulus of crushed salt is about 150 MPa and the final value at full consolidation is that of intact salt, or 20,626 MPa. If the mean stress in the crushed salt is assumed to change from zero to the lithostatic value of nearly 15 MPa compression over a 50-year period, the elastic strain rate can be computed to be about 6.3E-11 s^{-1} based on the initial bulk modulus and 4.6E-13 s^{-1} based on the final bulk modulus value. If a pressure of 0.1 MPa compression in the crushed salt is assumed and the initial density is used, a creep consolidation strain rate of about 2.3E-7 s^{-1} is computed. Thus, the elastic strain rate is about three to six orders of magnitude less than the creep consolidation strain rate. As the crushed salt consolidates, both the elastic and creep consolidation strain rates decrease. However, the effective pressure in the crushed salt also increases with time, which increases the creep consolidation strain rate. In addition, when the inert material is mixed with the crushed salt, the stiffness of the mixture is increased, which reduces the elastic strain rate. Therefore, neglecting the elastic strain rates appears to be a reasonable assumption and the relation for the volumetric creep strain of the mixture becomes

$$\dot{\epsilon}_v^c = v_0^s \dot{\epsilon}_{v_s}^c \tag{2-70}$$

where $\dot{\epsilon}_{v_s}^c$ is given by Equation 2-52.

2.3.2.2 Nonlinear Elastic Response of TRU Waste and Crushed Salt Mixtures

For the nonlinear elastic model, the derivation of the elastic constants for a mixture of two dissimilar materials is required. One material behaves nonlinearly and the other material is linear. Many different methods exist for representing the continuum properties of multiphase materials with different distributions of the phases. Maxwell's model considers randomly sized spheres of one material distributed in another (e.g., Parrott and Stuckes, [1975]). Other examples of property bounds established for multiphase materials may be found in Hashin and Shtrikman [1962], Corson [1974], and Milton [1982]. Corson [1974], referencing another researcher who used energy theorems of classical elasticity theory to establish bounds for effective bulk and shear moduli, states that his resultant bounds were precisely the volume-fraction average of the modulus of each phase (upper bound) and the inverse of the volume-fraction average of the inverse modulus (lower bound). Therefore, although many complex methods exist to establish bounds for the elastic moduli in a mixture, the simple rule of mixtures is relied upon because precise knowledge of the properties and the distribution of the phases in the two-component system is not available.

The rule of mixtures states that a given property for a mixture (Θ) is simply a function of the component properties (θ_i) weighted according to their volume

fractions (v_i). Parallel and series combinations are typical simple forms that may be stated mathematically as

$$\Theta = v_i\theta_i \tag{2-71}$$

$$\frac{1}{\Theta} = \frac{v_i}{\theta_i} \tag{2-72}$$

and $\Sigma v_i = 1$. These two mixture forms provide simple upper and lower bounds. Either Equation 2-71 or 2-72 could be used to formulate the effective moduli for the two-component mixture. Equation 2-71 is used to develop the moduli for the mixture, which gives the upper bound or higher stiffnesses. Thus, the elastic moduli for the mixture are

$$K = v_s K_s + v_m K_m \tag{2-73}$$

$$G = v_s G_s + v_m G_m \tag{2-74}$$

where

v_s = volumetric fraction of crushed salt
v_m = volumetric fraction of inert material
K_m = bulk modulus of the inert material
G_m = shear modulus of the inert material.

The functional form of the nonlinear elastic material model for crushed salt is described in Section 2.2.1 with the bulk (K_s) and shear (G_s) moduli defined by Equations 2-38 as

$$K_s = K_0 e^{K_1 \rho_s} \tag{2-75}$$

$$G_s = G_0 e^{G_1 \rho_s} \tag{2-76}$$

where K_0, K_1, G_0, and G_1 are material constants. The moduli for the inert material are assumed to be constant but the volume fraction and the moduli for the crushed salt will change with consolidation. Since the volume fractions for the compacting material mixture changes, the mass fractions of the components are the desirable input variables since they are constant. Thus, expressions for the mass fractions in terms of the component densities and volume fractions are required. The density of the crushed salt and the inert material may be expressed as

$$\rho_s = \frac{M_s}{V_s} = \frac{m_s M}{v_s V} = \frac{m_s \rho}{v_s} \tag{2-77}$$

$$\rho_m = \frac{M_m}{V_m} = \frac{m_m M}{v_m V} = \frac{m_m \rho}{v_m} \tag{2-78}$$

where

ρ_m = density of the inert material
ρ = density of the mixture
M_s = mass of salt
M_m = mass of inert material.

Solving Equations 2-77 and 2-78 for the volume fractions gives

$$v_s = \frac{m_s \rho}{\rho_s} \tag{2-79}$$

$$v_m = \frac{m_m \rho}{\rho_m} \tag{2-80}$$

The total volume of the mixture (V) at any time is

$$V = V_s + V_m \tag{2-81}$$

Equation 2-81 may also be written as

$$V = \frac{m_s M}{\rho_s} + \frac{m_m M}{\rho_m} \tag{2-82}$$

Dividing Equation 2-82 by the total mass gives

$$\frac{1}{\rho} = \frac{m_s}{\rho_s} + \frac{m_m}{\rho_m} \tag{2-83}$$

After algebraic manipulation, Equation 2-83 may be written

$$\rho = \frac{\rho_s \rho_m}{m_s \rho_m + m_m \rho_s} \tag{2-84}$$

Solving Equation 2-84 for the crushed salt density yields

$$\rho_s = \frac{m_s \rho \rho_m}{\rho_m - m_m \rho} \tag{2-85}$$

Substitution of Equation 2-85 into Equations 2-79 and 2-80 yields expressions for the volume fractions in terms of the mass fractions and densities

$$v_s = \frac{m_s \rho_m}{m_s \rho_m + m_m \rho_s} \tag{2-86}$$

$$v_m = \frac{m_m \rho_s}{m_s \rho_m + m_m \rho_s} \tag{2-87}$$

Similarly, the mass fractions can be expressed as

$$m_s = \frac{v_s \rho_s}{v_s \rho_s + v_m \rho_m} \tag{2-88}$$

$$m_m = \frac{v_m \rho_m}{v_s \rho_s + v_m \rho_m} \tag{2-89}$$

With the volume fractions given by Equations 2-86 and 2-87, the elastic moduli can be determined by substitution into Equations 2-73 and 2-74. The procedure given in Section 2.2.1 can then be followed to solve the nonlinear elastic mixture problem.

Now, expressions are needed for the final values of the bulk and shear moduli, which depend on the final volume fractions of the mixed materials when the void fraction is zero. If the void volume is considered to reside entirely in the crushed salt, the crushed salt volume (V_s) may be expressed as

$$V_s = V_v + V_{is} \tag{2-90}$$

where V_v and V_{is} are the volumes of the voids and the intact (solid) salt, respectively, and the total volume of the mixture is given in Equation 2-81. The porosity of the crushed salt (ϕ_s) is defined as

$$\phi_s = \frac{V_v}{V_s} = \frac{V_s - V_{is}}{V_s} = 1 - \frac{\rho_s}{\rho_{is}} \tag{2-91}$$

where ρ_{is} is the density of intact salt. The volume fraction of the crushed salt (v_s) is given by

$$v_s = \frac{V_v + V_{is}}{V} \tag{2-92}$$

From Equations 2-90, 2-91, and 2-92, we have

$$V_v = \phi_s V_s = \phi_s \{V_v + V_{is}\} = \phi_s v_s V \tag{2-93}$$

Using Equation 2-93, the porosity of the mixture (ϕ) is

$$\phi = \frac{V_v}{V} = \phi_s v_s \tag{2-94}$$

Since the sum of the volume fractions equals one, i.e.,

$$\phi + v_{is} + v_m = 1 \tag{2-95}$$

the volume fraction of salt is given as

$$v_{is} = 1 - \phi - v_m \tag{2-96}$$

Therefore, the final volume of the crushed salt V_s^f, which is the same as the volume of solid salt, is obtained when $V_v = 0$ which implies that $\phi_s = 0$ and $\phi = 0$

$$V_s^f = V_{is} = v_{is} V \tag{2-97}$$

Thus, the final volume of the mixture is

$$V^f = V_{is} + V_m = v_{is} V + V_m \tag{2-98}$$

The volume fraction of the mixture remaining after full consolidation (v^f) is obtained by dividing Equation 2-98 by the volume (V) giving

$$v^f = v_{is} + v_m = 1 - \phi \tag{2-99}$$

The final volume fractions for salt (v_{is}^f) and the inert material (v_m^f) are then determined as

$$v_{is}^f = \frac{v_{is}}{v^f} \tag{2-100}$$

$$v_m^f = \frac{v_m}{v^f} \tag{2-101}$$

The final density and moduli of the mixture can then be determined from mixture theory as

$$\rho^f = v_{is}^f \rho_{is} + v_m^f \rho_m \tag{2-102}$$

$$K^f = v_{is}^f K_{is} + v_m^f K_m \tag{2-103}$$

$$G^f = v_{is}^f G_{is} + v_m^f G_m \tag{2-104}$$

2.3.3 Material Properties for Crushed Salt Mixtures

2.3.3.1 Crushed Salt/Bentonite Mixture

The functional forms of the crushed salt/bentonite mixture constitutive relations were selected to be the same as those present in Section 2.2 for crushed salt. However, the material parameters were modified based on available information to be more representative of the crushed salt/bentonite mixture. The nonlinear elastic parameter values describing the nonlinear moduli for a 70/30 percent by weight crushed salt/bentonite mixture defined in Equation 2-38 are given in Table 2-4. Table 2-4 also gives the initial and final or intact densities for the crushed salt/bentonite mixture. The final or intact material density was taken to be 2,260 kg/m^3. Pfeifle [1990] gives a value of 2,266 kg/m^3 for a 70/30 percent by weight crushed salt/bentonite mixture, assuming a solid density for salt of 2,120 kg/m^3 and a solid density for bentonite of 2,700 kg/m^3. The initial material density was selected such that the initial porosity of the crushed salt/bentonite mixture was the same as that assumed for the crushed salt. Because of the lack of test data for the elastic properties of the crushed salt/bentonite mixtures, the parameter values for the nonlinear elastic moduli were assumed to be the same as crushed salt. However, the K_1 and G_1 parameters were computed based on the final density value such that the ultimate moduli values (K_f and G_f) are reached when the mixture attains the final density.

Table 2-5 presents the parameter values for the creep consolidation constitutive equation given in Equation 2-52. The crushed salt/bentonite material parameters are taken from Pfeifle [1990]. The material parameter values for the creep consolidation model for the crushed salt/bentonite experiments conducted by Pfeifle [1990] at various moisture contents are given in Table 2-5. The property values labeled *Selected* represent the parameter value set chosen to represent the crushed

salt/bentonite backfill. These parameter values were selected because they represent the three tests performed by Pfeifle [1990] reasonably well; however, they do not represent the tests well over a wide range in pressures as discussed in the next paragraphs.

Table 2-4. Nonlinear Elastic Material Parameters for Crushed Salt/Bentonite

Parameter	Units	Value
K_0	MPa	0.01760[a]
K_1	m^3/kg	0.00945[b]
G_0	MPa	0.01060[a]
G_1	m^3/kg	0.00945[b]
K_f	MPa	20,626[a]
G_f	MPa	12,423[a]
ρ_0	kg/m^3	1,478.5[c]
ρ_f	kg/m^3	2,260[d]

(*a*) Assumed identical to crushed salt (see Table 2-2).

(*b*) Computed from Equation 2-38 using ρ_f with K_f and G_f values.

(*c*) Computed so that initial porosity was identical to crushed salt.

(*d*) Engineering estimate.

Table 2-5. Creep Consolidation Model Parameter Values for Crushed Salt/Bentonite

Test I.D.	Moisture Content (%)	Hydrostatic Pressure (MPa)	Parameter Values[a]		
			A ($m^3 \cdot kg^{-1} \times 10^{-3}$)	B_0 ($kg \cdot m^{-3} \cdot s^{-1} \times 10^{21}$)	B_1 (MPa^{-1})
CS1	5.3	3.45 to 14	-33.9	0.972	.693
CS4	5.24	3.45 to 14	-34.5	1.021	.509
CS3	9.97	3.45 to 7	-30.3	0.970	.084
Selected Crushed Salt/ Bentonite Values			-34.5	1.000	.600

(*a*) CS1, CS4, and CS3 parameter values taken from Pfeifle [1990].

Figure 2-1 plots the log of the volumetric strain rate resulting from the parameter sets given in Table 2-5 for various fractional densities with an assumed applied pressure of 15 MPa. In this series of curves, the selected parameter values for crushed salt/bentonite seem to fairly well represent the parameter values given by Pfeifle [1990]. Since very little pressure build up is observed in the crushed salt until the backfill is nearly compacted, the parameter sets are also illustrated for lower pressures. Figure 2-2 illustrates the same information presented in Figure 2-1 except that the assumed applied pressure is 0.05 MPa. In this series of curves, the curve for the selected parameter values is similar to the lower curve that was generated with the parameter values labeled *CS4* in Table 2-5. Also note that the volumetric strain rates for the crushed salt/bentonite are higher than the crushed salt for low values of fractional density.

Figure 2-3 compares the change in volumetric strain rate with time for crushed salt and crushed salt/bentonite bodies under a constant pressure of 0.05 MPa. The parameter values for the crushed salt model given in Table 2-3 were derived by Sjaardema and Krieg [1987] based on hydrostatic consolidation tests conducted by Holcomb and Shields [1987] on crushed WIPP salt with added water. The test duration for these crushed salt tests was typically 23 days. The parameter values for the crushed salt/bentonite model given in Table 2-5 were derived by Pfeifle [1990] from multistage tests on crushed salt/bentonite mixtures with added water. Pfeifle's test durations ranged from 272 to 305 days, which included a final permeability measurement stage. The duration of Stage One in the tests ranged from 70 to 118 days. The curves in Figure 2-3 were generated using the analytical solution for creep consolidation given in Callahan [1990]. Figure 2-3 shows that the volumetric strain rate for the crushed salt/bentonite is higher than that of the crushed salt during early time with the strain rates for both decreasing with time. After about .01 year, the strain rate for the crushed salt/bentonite becomes less than the crushed salt strain rate.

2.3.3.2 Crushed Salt/TRU Waste Mixture

Material parameter values for crushed salt are given in Section 2.2.4. Therefore, to describe material properties for the crushed salt/TRU waste mixture, only the TRU waste properties need to be defined. Subsequently, mixture properties can be computed from the equations derived in Section 2.3.2.2. The TRU waste mixed with the crushed salt is assumed to consist of shredded metal wastes. The simulated metallic wastes tested by Butcher et al. [1991] included cut up steel, copper, lead, and aluminum scrap, and Butcher et al. [1991] assumed a solid density of 7,360 kg/m^3. Additional discussion of probable metallic waste composition is given by Butcher [1989] where the assumed solid density of metallic waste is 7,860 kg/m^3. Table 2-6 gives properties and assumed volume fractions of steel, aluminum, copper, lead, and tantalum [Butcher, 1990] used in this study. The composite material properties given in Table 2-6 are assumed to be representative of the shredded metallic waste. For crushed salt, an initial density of 1,400 kg/m^3 is assumed. The

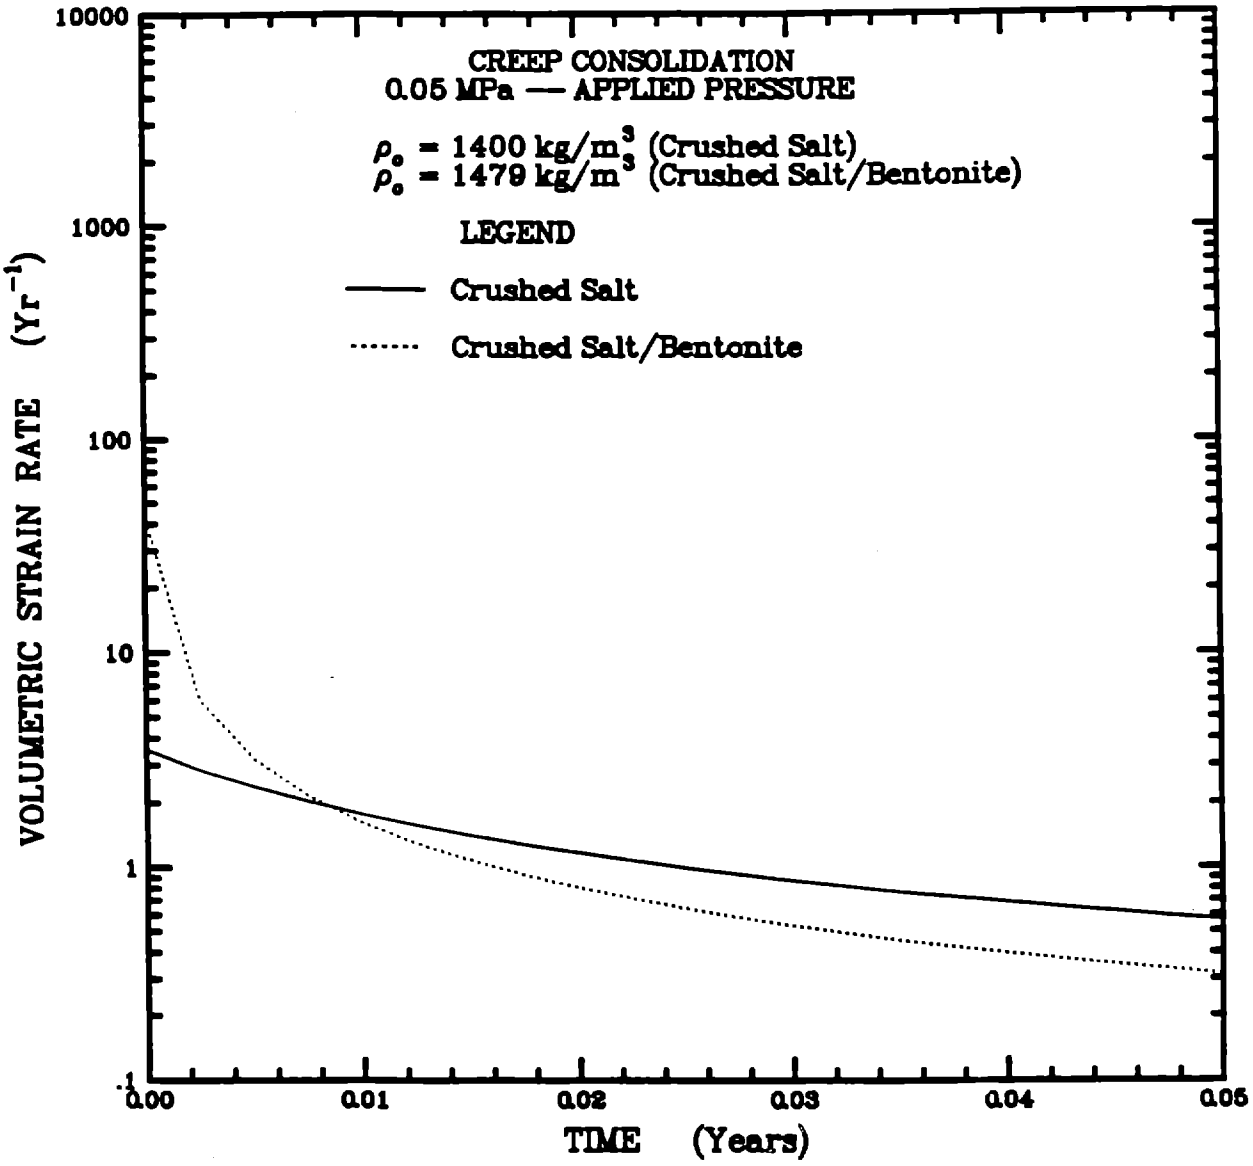

Figure 2-3. Change in Volumetric Strain Rate With Time for an Applied Pressure of 0.05 MPa.

initial crushed salt/shredded metal waste mix is assumed to be 80/20 percent by volume.

Table 2-6. Metallic Waste Components Properties

Component	Volume (%)	Density ($kg \times m^{-3}$)	Modulus of Elasticity (GPa)	Poisson's Ratio (—)	Shear Modulus[a] (GPa)	Bulk Modulus[b] (GPa)
Steel	64	7,860[c]	207[c]	0.27[c]	81	150
Aluminum	14	2,700[d]	69[d]	0.33[c]	26	68
Copper	11	8,960[d]	117[d]	0.34[c]	44	122
Lead	7	11,350[d]	14[d]	0.30[e]	5	12
Tantalum	4	16,600[d]	186[d]	0.27[e]	73	135
Composite[f]	100	7,845	163	0.29	64	125

(*a*) Computed using $\frac{E}{2(1+\nu)}$.

(*b*) Computed using $\frac{E}{3(1-2\nu)}$.

(*c*) McClintock and Argon [1966].

(*d*) Lynch [1974].

(*e*) Engineering estimate.

(*f*) Computed using Equation 2-71.

From the given properties, the initial density and mass fractions can be computed using Equations 2-84, 2-88, and 2-89. Substituting the given values yields the initial density of the mixture $\rho_0 = 2,690\ kg/m^3$, mass fraction of the salt $m_s = 0.417$, and mass fraction of the shredded metallic waste $m_m = 0.584$. From Equations 2-91 and 2-94, initial values for the porosities of the salt and the mixture are found to be $\phi_s = 0.346$ and $\phi = 0.277$. From Equation 2-96, the volume fraction of solid salt is $v_{i_s} = 0.523$. Therefore, from Equations 2-99, 2-100, and 2-101, respectively, $v^f = 0.723$, $v^f_{i_s} = 0.724$, and $v^f_m = 0.277$. From Equations 2-102, 2-103, and 2-104, respectively, the final density is $\rho^f = 3,720\ kg/m^3$, the final bulk modulus is $K^f = 49,500$ MPa, and the final shear modulus is $G^f = 26,600$ MPa.

2.4 TRU WASTE

Two TRU waste forms are considered in this section: (1) a mixture of metallic, combustible, and sludge wastes and (2) a vitrified TRU waste. Two material models are required to characterize the behavior of these two TRU waste forms: (1) a

nonlinear elastic model to represent the composite TRU waste mixture and (2) a linear elastic model to represent the vitrified waste.

TRU waste forms are nonstandard and considerably variable in nature and quantity (e.g., see Butcher [1989]). TRU waste drums will be randomly placed within storage rooms at the WIPP site without regard to waste type. Wastes types may also be mixed within individual drums. Because of this random placement and mixture of wastes, it is necessary to assume that the waste drums can be characterized by a composite (or mechanically equivalent) waste drum. Therefore, a nonlinear elastic material model is developed to represent the composite TRU waste. Although TRU waste compaction is known to be irreversible, it is modeled as a nonlinear elastic material recognizing that the model is valid only if the load on the waste is monotonically increasing.

Vitrification is a possible waste treatment. Therefore, a model is developed to represent the glass-like substance resulting from a TRU vitrification process.

2.4.1 Nonlinear Elastic

As a first attempt, the nonlinear elastic model described in Section 2.2.2 was used to describe the behavior of a composite TRU waste. However, the functional form presented for the bulk modulus (Equation 2-38) did not adequately fit the simulated TRU waste compaction data. Therefore, an alternate functional form for the nonlinear elastic model was developed that fits the simulated TRU waste compaction data better. This model is

$$\sigma_a = \frac{1}{\kappa} ln(\frac{\phi}{\phi_0}) \tag{2-105}$$

where

σ_a = axial stress, $\sigma_a = 3\sigma_m$
σ_m = mean stress
κ = material parameter
ϕ = porosity
ϕ_0 = initial porosity.

The assumption stated above (i.e., $\sigma_a = 3\sigma_m$) is significant. The need for this assumption stems from the fact that the experiments were conducted on the compaction of simulated waste in rigid steel sleeves [Butcher et al., 1991] and only the axial stress component was measured. To evaluate the parameter values for the TRU waste model, all three stress components need to be known. Two bounding assumptions to infer values for the lateral stress components are (1) the lateral stress components are zero (i.e., $\sigma_a = 3\sigma_m$) and (2) the lateral stress components are equal to the axial stress (i.e., $\sigma_a = \sigma_m/3$). Assumption 1 represents an unconfined test, and Assumption 2 represents a hydrostatic test. Neither assumption is correct

in the sense that it represents the conditions in the experiment; however, the two assumptions bound the true stress conditions. The first assumption was adopted because it provides the less stiff representation of the TRU waste. The less stiff representation is felt to be more conservative because it provides less resistance to room closure and lower back pressure on the surrounding backfill, which increases the time required to obtain lower porosities in the backfill surrounding the TRU waste.

In terms of porosity, Equation 2-105 may be stated as

$$\phi = \phi_0 \exp(\kappa \sigma_a) \tag{2-106}$$

Porosity and density are defined as

$$\phi = 1 - \frac{\rho}{\rho_f} \tag{2-107}$$

$$\rho = \frac{\rho_0}{1 + \epsilon_v} \tag{2-108}$$

where

ρ = current density
ρ_0 = initial density
ρ_f = final density or intact material density
ϵ_v = volumetric strain.

Parameters ϕ_0 and κ are found by fitting Equation 2-106 to axial stress/porosity data (Appendix A) using least squares methods. Equation 2-106 implies an initial porosity of ϕ_0 and a porosity that approaches zero as the compressive stress (compressive stress is taken to be negative) approaches infinity.

From the TRU waste compaction equation, expressions for the moduli need to be derived to complete the nonlinear elastic model. The tangent bulk modulus (K) can be stated as

$$K = \frac{d\sigma_m}{d\epsilon_v} = \frac{d\sigma_m}{d\phi} \frac{d\phi}{d\rho} \frac{d\rho}{d\epsilon_v} \tag{2-109}$$

Performing the differentiation indicated in Equation 2-109 on Equation 2-105 results in

$$K = \frac{\rho^2}{3\kappa\rho_0(\rho_f - \rho)} \tag{2-110}$$

From Equation 2-110, the initial bulk modulus (K_i) is

$$K_i = \frac{\rho_0}{3\kappa(\rho_f - \rho_0)} \tag{2-111}$$

Also note that the bulk modulus is infinite when the final density is reached. Therefore, from a practical standpoint, it is necessary to prescribe a final bulk modulus

value that corresponds to an intact material density that is less than ρ_f when performing analyses. Equation 2-110 may also be expressed in terms of the porosity as

$$K = \frac{(1-\phi)^2 \rho_f}{3\kappa\phi\rho_0} \tag{2-112}$$

To derive a corresponding functional form for the shear modulus (G), a constant value for Poisson's ratio of $\nu = 0.25$ is assumed. Poisson's ratio expressed in terms of K and G is

$$\nu = \frac{3K - 2G}{6K + 2G} \tag{2-113}$$

Substituting the value for Poisson's ratio into Equation 2-113 and solving for G yields

$$G = \frac{3}{5}K \tag{2-114}$$

Therefore, using Equation 2-110, the expression for the shear modulus is

$$G = \frac{\rho^2}{3\lambda\rho_0(\rho_f - \rho)} \tag{2-115}$$

where $\lambda = \frac{5}{3}\kappa$.

With the nonlinear elastic moduli described by Equations 2-110 and 2-115, the nonlinear elastic model is completed using the procedure described in Section 2.2.1.

2.4.2 Vitrified Waste

Vitrified waste is assumed to be a linear elastic material. Therefore, the constitutive relation given in Section 2.1.1 also applies to the vitrified waste.

2.4.3 Material Properties for TRU Waste

The laboratory data used to determine the constitutive parameters for TRU waste compaction were obtained from Sandia National Laboratories (SNL). Tests were performed on three general types of simulated waste: combustible, metallic, and sludge wastes. The data consist of axial stress (σ_a) versus porosity (ϕ) pairs for each of the waste types and are reproduced in Appendix A. The assumption discussed in Section 2.4.1 (i.e., $\sigma_a = 3\sigma_m$) is applied to interpret and use the axial stress data. The experimental data and their corresponding fits to Equation 2-106 are shown in Figure 2-4. Because of the assumption discussed above, ordinate values in Figure 2-4 need to be divided by three to obtain information relating mean stress to porosity. Equation 2-106 fits the data quite well over most of the stress range; however, as seen in Figure 2-4, the fits are rather poor in the low-stress regime.

Table 2-7 contains parameters describing the individual waste types. The average solid densities for each of the waste types were obtained from Butcher et al.

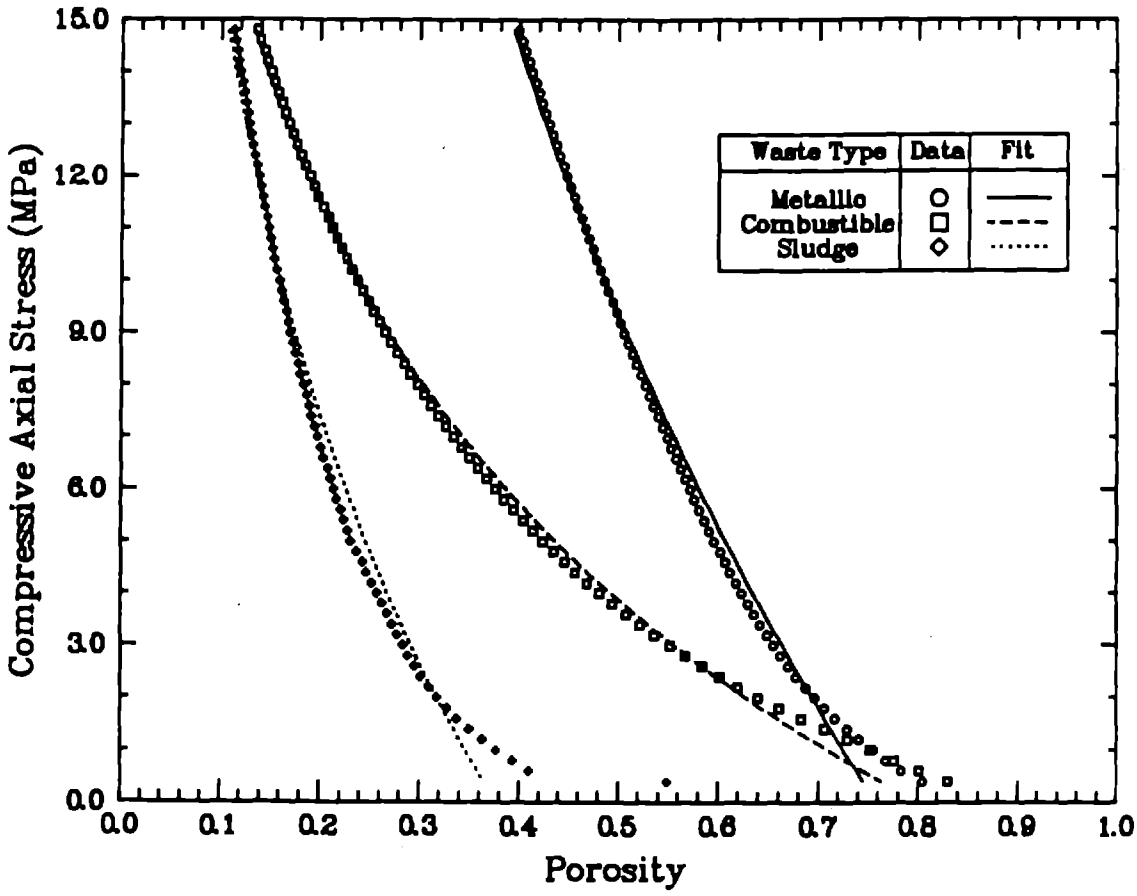

Figure 2-4. Compaction Data (Appendix A) and Fits for Individual Waste Types.

[1991]. The model parameters (ϕ_0 and κ) were determined for each of the waste types by fitting the experimental data to Equation 2-106. Initial densities were calculated from the solid density values and the fitted initial porosity values for each waste type using the following relationship:

$$\rho_0 = \rho_f (1 - \phi_0) \tag{2-116}$$

Table 2-7. Individual Waste Type Characteristics

Waste Type	Solid Density ρ_f (kg/m^3)	Initial Porosity ϕ_0	κ (MPa^{-1})	Initial Density ρ_0 (kg/m^3)
Combustible	1,920	0.801	0.121	383
Metallic	4,000	0.758	0.044	967
Sludge	2,370	0.377	0.085	1,480

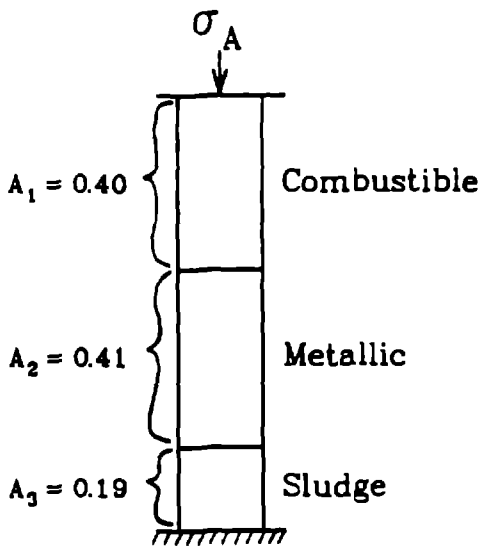
2.4.3.1 Models for Composite Waste Canisters

In this section, the waste drums are characterized by a composite (or mechanically equivalent) waste drum. A composite TRU waste drum as determined by Butcher et al. [1991] initially contains 40 percent combustible waste, 41 percent metallic waste, and 19 percent sludge waste by volume.

Two one-dimensional methods of combining the individual waste characteristics together to form a composite waste model are examined. The first model assumes that the three individual waste types are analogous to three nonlinear springs in series. The second model assumes that the three individual waste types are analogous to three nonlinear springs in parallel. Diagrams of the series and parallel models are shown in Figures 2-5 and 2-6, respectively. The following sections describe how stress/porosity data is generated and fitted to the nonlinear elastic functional form describing the waste.

Series Model

In the series model (Figure 2-5), the initial length of each spring is proportional to the initial volume fraction of the waste type it represents. Axial stress is assumed to be the same in all three materials and is equivalent to the stress in the composite model. Stress/porosity data pairs were generated at stress levels ranging from 0 to −25 MPa. The porosity for each of the individual waste types was found using Equation 2-106 and the parameter values in Table 2-7. The porosity of the

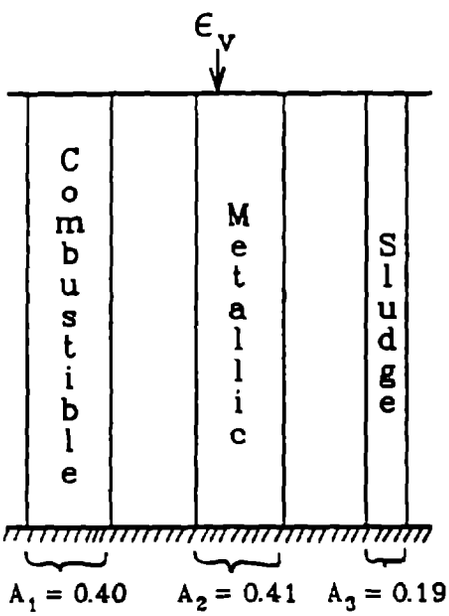


$$\sigma_A = \sigma_1 = \sigma_2 = \sigma_3$$

$$\epsilon_v = \frac{A_1\epsilon_1 + A_2\epsilon_2 + A_3\epsilon_3}{A_1 + A_2 + A_3}$$

Note: Subscripts 1, 2, and 3 refer to the three waste components.

Figure 2-5. Composite Series Model.



$$\sigma_A = \frac{A_1\sigma_1 + A_2\sigma_2 + A_3\sigma_3}{A_1 + A_2 + A_3}$$

$$\epsilon_v = \epsilon_1 = \epsilon_2 = \epsilon_3$$

Note: Subscripts 1, 2, and 3 refer to the three waste components.

Figure 2-6. Composite Parallel Model.

composite series model was determined from

$$\phi = \frac{\text{Void Volume}}{\text{Total Volume}} = \frac{V - V_s}{V} \tag{2-117}$$

where V is the total volume at the current stress and is determined by

$$V = V_0 \sum_{i=1}^{3} \frac{A_i \rho_{0_i}}{\rho_{s_i}(1 - \phi_i)} \tag{2-118}$$

and V_s is the volume of solid materials and is determined from the individual wastes by

$$V_s = V_0 \sum_{i=1}^{3} \frac{A_i \rho_{0_i}}{\rho_{s_i}} \tag{2-119}$$

where

V_0 = initial volume of composite waste
A_i = initial volume percentage of waste type i
ρ_{0_i} = initial density of waste type i
ρ_{s_i} = solid density of waste type i
ϕ_i = porosity of waste type i, determined from Equation 2-106.

Parallel Model

The parallel model (Figure 2-6) assumes that the cross-sectional area of each spring is proportional to the original volume fraction of the waste type it represents. Each waste type is assumed to strain the same amount. Stress/porosity data pairs were generated at volumetric strain increments of the composite waste. Since the volumetric strain of each of the individual wastes is equivalent to the volumetric strain of the composite waste, the porosity of each component can be found from the following relationship

$$\phi_i = 1 - \frac{\rho_{0_i}}{\rho_{s_i}(1 + \epsilon_v)} \tag{2-120}$$

where ϵ_v is the volumetric strain of the composite model. Note that since each of the individual wastes is modeled using Equation 2-106, the composite model can only be strained until one of the individual wastes approaches zero porosity. At this point, stress approaches infinity. In this case, the sludge waste is the first to approach zero porosity.

Once the individual porosities are known, Equations 2-117, 2-118, and 2-119 can be used to determine the porosity of the composite waste. The stress in each individual waste type can be found from Equation 2-106 as

$$\sigma_{a_i} = \frac{\ln(\phi_i) - \ln(\phi_{0_i})}{\kappa_i} \tag{2-121}$$

The composite stress can then be determined from the individual stresses as

$$\sigma_a = \frac{\sum_{i=1}^{3} A_i \sigma_{a_i}}{\sum_{i=1}^{3} A_i} = \sum_{i=1}^{3} A_i \sigma_{a_i} \tag{2-122}$$

2.4.3.2 Results

The generated stress/porosity data pairs for both models were fitted to the nonlinear functional form in Equation 2-106. The resulting parameters are shown in Table 2-8. Figure 2-7 shows the generated stress/porosity data pairs and the corresponding least squares fit for each model. The series model fits the nonlinear elastic functional form very well except at very low stresses. The parallel model, however, does not fit the functional form very well. Therefore, the series model was selected to represent the TRU waste. As the compressive stress approaches infinity, the functional form in Equation 2-106 approaches zero porosity; whereas, the parallel model data approaches a porosity of 0.52.

Table 2-8. Composite Waste Characteristics

Model	Solid Density ρ_f (kg/m^3)	Initial Porosity ϕ_0	κ (MPa^{-1})	Initial Density ρ_0 (kg/m^3)
Series	2,790	0.650	0.068	978
Parallel	2,790	0.637	0.169	1,010

The solid density of the composite waste is determined from the relationship

$$\rho_f = \frac{m}{V_s} = \frac{V_0 \sum_{i=1}^{3} A_i \rho_{0_i}}{V_s} \tag{2-123}$$

where m is the mass of the composite waste and the solid volume, V_s, is found using Equation 2-119. Equation 2-116 can then be used to determine the initial density of the composite waste for each model. The calculated values of initial and solid densities for the two models are shown in Table 2-8.

2.4.3.3 Composite TRU Waste Properties

Series and parallel formulations are derived in the preceding sections to represent the composite TRU waste package. Since the series representation provides the best

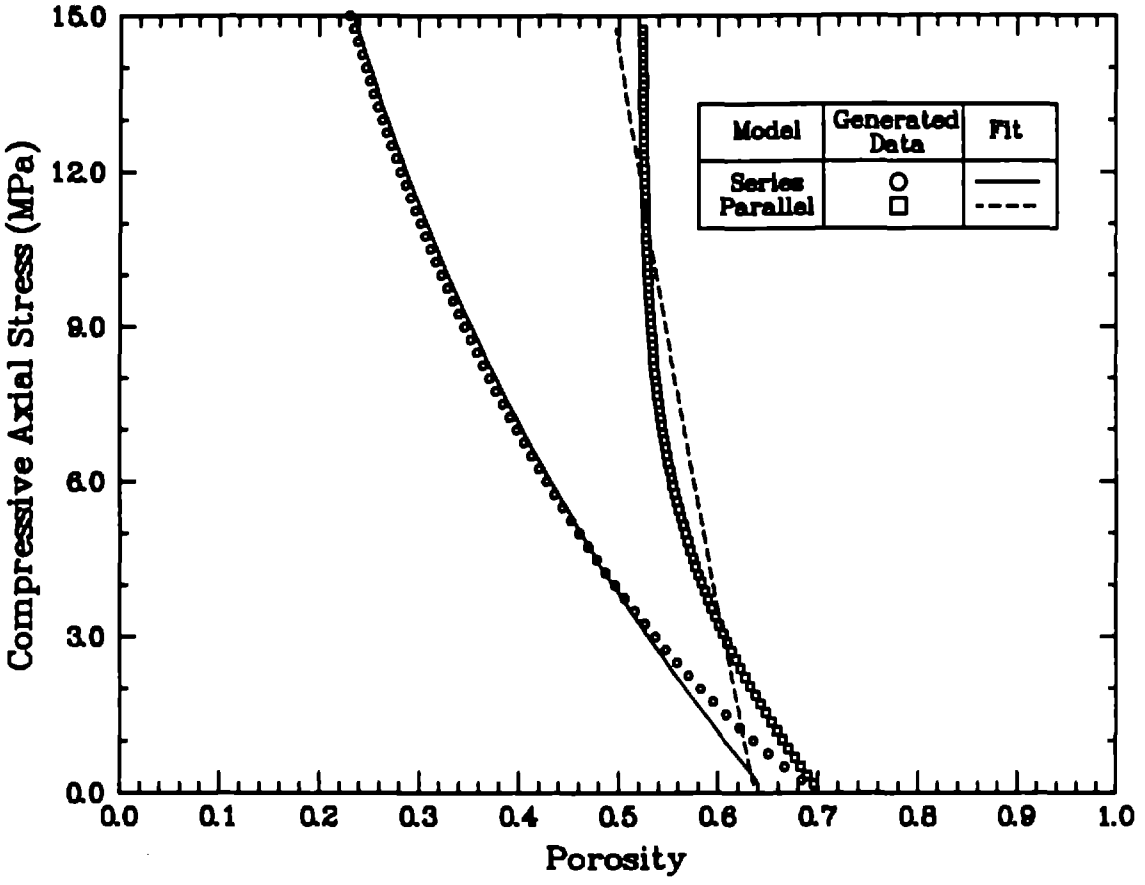


Figure 2-7. Generated Data and Fits for Composite Models.

fit to the simulated TRU waste compaction data, parameter values generated using the series model are chosen to represent the TRU waste. However, the parameter values require modification to represent the selected composite TRU waste. The composite TRU waste drum as determined by Butcher et al. [1991] initially contains 40 percent combustible waste, 41 percent metallic waste, and 19 percent sludge waste by volume. The drum weights and the average solid densities for each of the three waste types is taken from Butcher et al. [1991] and are shown in Table 2-9. The volume of the drum used for encapsulating the wastes is 0.21 m^3 (55 gal). The volume of the solids is calculated by dividing the drum weight by the solid density, ρ_f (i.e., the density of fully compacted, consolidated waste). The initial density, ρ_o, is calculated by dividing the drum weight by the drum volume.

Table 2-9. TRU Waste Drum Characteristics

Waste Type	Drum Weight (kg)	Solid Density (kg/m^3)	Solids Volume (m^3)	Initial Density (kg/m^3)
Combustible	77.0	1,920	0.0401	367
Metallic	101.5	4,000	0.0254	483
Sludge	218.0	2,370	0.0920	1,038
Composite[a]	114.0	2,593	0.0439	542

(a) Based on Volumetric Distribution of 40 percent Combustible, 41 percent Metallic, and 19 percent Sludge.

Using the percentage volumetric distribution of waste types, the volume of solids in the "typical composite TRU waste package" is 0.044 m^3. The weight and initial density of the composite TRU drum are 114 kg and 542 kg/m^3, respectively. The solid density of the typical composite TRU waste drum (fully consolidated) can then be calculated to be 2,593 kg/m^3. The initial porosity (void fraction), ϕ_o, is calculated from the Equation 2-120, which yields a value of 79 percent.

As shown in Table 2-8, the series model representation corresponds to an initial porosity of 0.65 and an initial density of 978 kg/m^3; whereas, the selected representative composite TRU waste has an initial porosity of 0.79 and initial density of 542 kg/m^3. Thus, a difference exists between the series model representation of the TRU waste and the described typical composite TRU waste package. The series model results in a poor estimate of initial density and porosity of the typical composite TRU waste package. If the appropriate initial density and porosity values of the typical composite TRU waste package are used, the least squares curve of the series model will not be followed. As a compromise resolution to this problem, the appropriate initial density value was deemed the most important parameter, and the product of κ and initial density was maintained constant. Thus, ρ_0=542 kg/m^3

and κ=0.122 MPa^{-1} was used for the selected composite TRU waste. In addition, since the moduli are infinite when the final density is reached, a final density value of 2,599 kg/m^3 was selected so that the actual final density of 2,593 kg/m^3 could be attained without causing numerical difficulties.

In summary, the composite TRU waste has an initial density of 542 kg/m^3, an initial porosity of 79 percent, and a final density of 2,599 kg/m^3. Equations 2-110 and 2-115 are used to compute the moduli as a function of density. The parameter values used in these equations are κ=0.1224 MPa^{-1} and λ=0.2040 MPa^{-1}. Substitution of these values into Equations 2-110 and 2-115 gives values for the bulk and shear moduli of 5,442 MPa and 3,265 MPa, respectively, at a density of 2,593 kg/m^3.

2.4.3.4 Vitrified Waste Properties

The linear elastic parameter values for the constitutive relation given in Equation 2-3 are given in Table 2-10. The vitrified waste material parameters are taken from McClintock and Argon [1966] for glass. Density of glasses range from about 2,200 to 3,800 kg/m^3.

Table 2-10. Elastic Constants for Vitrified Waste

Parameter	Units	Value
E	MPa	67,560
ν	—	0.25

3.0 FINITE ELEMENT IDEALIZATION OF DISPOSAL ROOM

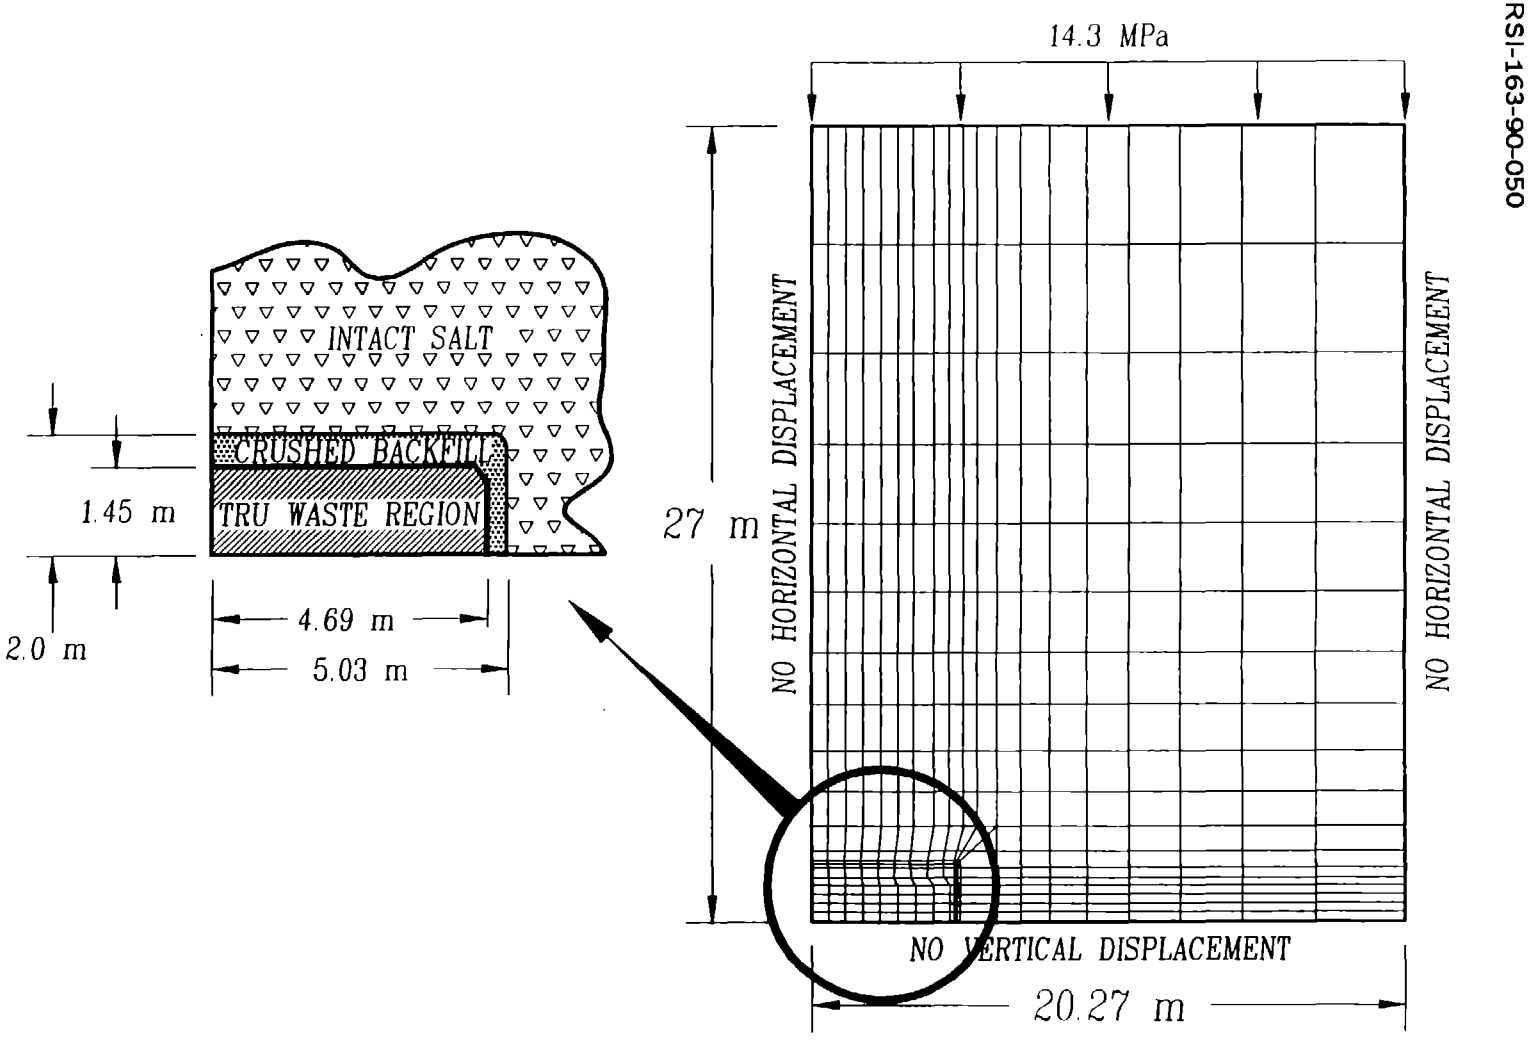
The finite element program SPECTROM-32 was used in this study to analyze the structural behavior of a hypothetical WIPP room for storing nonheat-producing transuranic (TRU) waste. The configuration modeled consists of an infinite series of disposal rooms 10.06 m wide by 4.0 m high and separated by pillars spaced at 40.54 m on center in the horizontal direction. Because one of the objectives of this study was to obtain results for comparison with the results obtained from similar calculations performed by Weatherby [1989] using SANCHO, geometric simplifications were made for consistency. The geometric simplifications made include:

1. The rooms were assumed to be located in a homogeneous layer of bedded salt thus eliminating the need to model the numerous stratigraphic layers present at the WIPP.

2. The deformation was assumed to be symmetric about a horizontal plane that passes through the center of the rib. Hence, the modeled region consists of the material above the symmetry plane.

3. The vertical extent of the region to be modeled was limited to 27 m above the room centerline. A boundary located this close to an excavation can be expected to influence the results; however, comparisons of the different backfill scenarios should not be compromised.

The finite element mesh used for all of the calculations presented in this report is shown in Figure 3-1. The finite element mesh contains 400 nodes and 399 four-node, quadrilateral elements. The finite element mesh is composed of three distinct regions that were used to represent the materials necessary to analyze the different room scenarios. The room detail given in Figure 3-1 shows the regions used to represent the TRU waste (if present) and the backfill materials. Region One is approximately a 4.69 m wide by 1.45 m high area in the lower left corner of the mesh. This model region represents the space occupied by the TRU waste. Region Two surrounds Region One and extends to the boundary of the room surface. Region Two was used to represent the backfill material that covers the waste. Regions One and Two comprise the disposal room and the remaining region represents the intact salt in the vicinity of the disposal room. The corners of the disposal room were assumed to be round (0.23 m radius) to match those at the WIPP site. The cross-sectional area of the waste and backfill regions are 6.77 m^2 and 3.28 m^2, respectively, yielding the total cross-sectional area for one-fourth of the disposal room of approximately 10.05 m^2. Symmetry conditions require no displacements normal to the boundary along the bottom, left, and right edges of the mesh. These kinematic constraints were prescribed as the boundary conditions for the mesh. The temperature throughout the modeled region was specified as 300 K.



RSI-163-90-050

Figure 3-1. Finite Element Mesh of Disposal Room.

The initial stress field before excavation was assumed to be a homogeneous, lithostatic state of stress. The magnitude of the initial stress field was defined by prescribing a superincumbent overburden traction of 14.3 MPa as shown in Figure 3-1. Gravitational forces were neglected with lateral earth pressure coefficients equal to one. Therefore, the initial state of stress everywhere in the defined problem region was $\sigma_x = \sigma_y = \sigma_z$ =−14.3 MPa. The initial stress condition for each of the analyses following excavation was established by excavating the disposal room into the host medium under the assumed lithostatic stress condition. Subsequently, the backfill was emplaced under stress-free conditions (i.e., body forces were neglected in the backfill). As a consequence of the assumed symmetry condition about the bottom boundary, the waste in the finite element model is located in the center of the room and is surrounded on all four sides by the backfill material. In the actual configuration, the waste will rest on the floor of the room and be surrounded by the backfill material on three sides.

4.0 RESULTS OF DISPOSAL ROOM ANALYSES

In this chapter, results are presented for six different room emplacement scenarios. Because these results are based on mechanical properties derived from a limited number of experiments and the constitutive models considered are currently in the development stage, results should be tempered with the validity of the specific properties and constitutive relations used to produce them. Numerical simulations of the different room emplacement scenarios were conducted assuming the following room contents.

1. Room completely filled with crushed salt.
2. Room completely filled with a 70 percent crushed salt — 30 percent bentonite (by weight) mixture.
3. TRU waste covered with crushed salt.
4. TRU waste covered with a 70 percent crushed salt — 30 percent bentonite (by weight) mixture.
5. An 80 percent crushed salt — 20 percent shredded metallic waste (by volume) mixture covered with crushed salt.
6. Vitrified waste covered with crushed salt.

The constitutive relations and material properties of the intact salt, backfill materials, and wastes used for these calculations are given in Chapter 2 and the finite element idealization is discussed in Chapter 3. In each of these analyses, the backfill and TRU waste were stress-free in the room at the beginning of the simulation (time = 0), and the creep deformation was simulated for 200 years. Additional details of each analysis and specific results are provided in the remainder of this chapter. Appendix B provides a comparison of selected results obtained from this study and those obtained by Weatherby [1989] and Weatherby and Brown [1990] using SANCHO for the first three aforementioned analyses. Appendix C includes history plots of void fraction and mean stress for each of the analyses.

4.1 ROOM FILLED WITH CRUSHED SALT

The closure of a room filled with crushed salt was analyzed assuming an initial density for the crushed salt to be approximately 65 percent of the intact density of salt. The initial and fully compacted densities specified for the crushed salt were 1,400 kg/m^3 and 2,140 kg/m^3, respectively. This corresponds to an initial void fraction of approximately 35 percent. During the course of the simulation, the volume of the crushed salt backfill was sufficiently reduced such that all of the

voids were removed and the density of the crushed salt reached the intact density of salt. When crushed salt elements attained the intact salt density, the crushed salt elements were changed to a creeping material obeying the Munson-Dawson constitutive model. The Munson-Dawson model parameter values used are the same as those for intact salt given in Chapter 2.

The room closure history of the disposal room backfilled with crushed salt is shown in Figure 4-1. In this figure and throughout this report, the horizontal closure is the change in the width at the midheight of the room expressed as a percentage of the original room width. Similarly, the vertical closure is the change in the height of the room at the center of the roof expressed as a percentage of the original room height. The maximum horizontal and vertical closures obtained for this analysis are 11 percent and 28 percent, respectively.

The void reduction in the disposal room expressed as a percentage of the initial void volume is shown in Figure 4-2 as a function of time. In this figure and throughout this report, the void reduction is the difference between the initial void volume and the current void volume expressed as a percentage of the initial void volume. Thus, the void reduction value will always be zero at the beginning of an analysis and will increase to 100 percent when the material becomes fully consolidated (voids are no longer present). The void reduction values were computed from the following relationship.

$$v = \frac{V_v^o - V_v}{V_v^o} \tag{4-1}$$

where

v = the void reduction in the element or region

V_v = the void volume in the element or region

V_v^o = the initial void volume inside the element or region.

As shown in Figure 4-2, 95 percent of the original void in the room is eliminated after approximately 19 years. The average void fractions presented in Appendix C were calculated using the following relationship:

$$v_f^o \equiv \frac{V_v}{V^o} = \frac{V_v^o + \Delta V}{V^o} \tag{4-2}$$

where

v_f^o = the void fraction in the element or region

V^o = the original volume of the element or region

ΔV = the difference between the current volume and the initial volume inside the element or region.

RSI-163-90-051

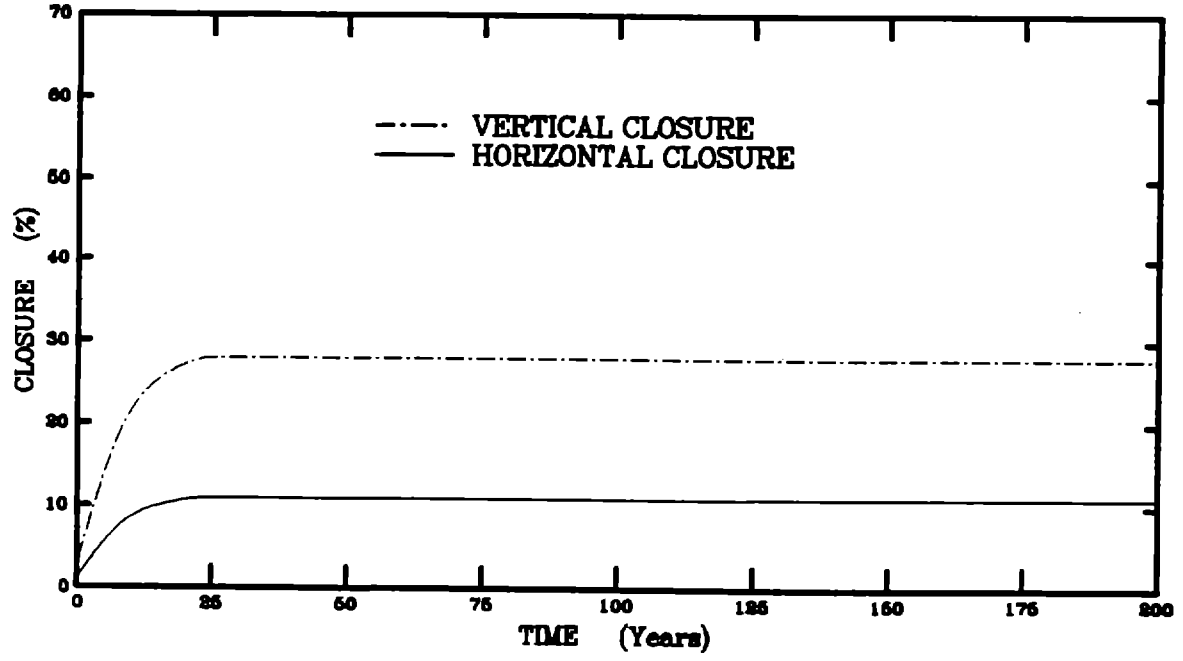


Figure 4-1. Room Closure History of a Disposal Room Filled With Crushed Salt.

RSI-163-90-052

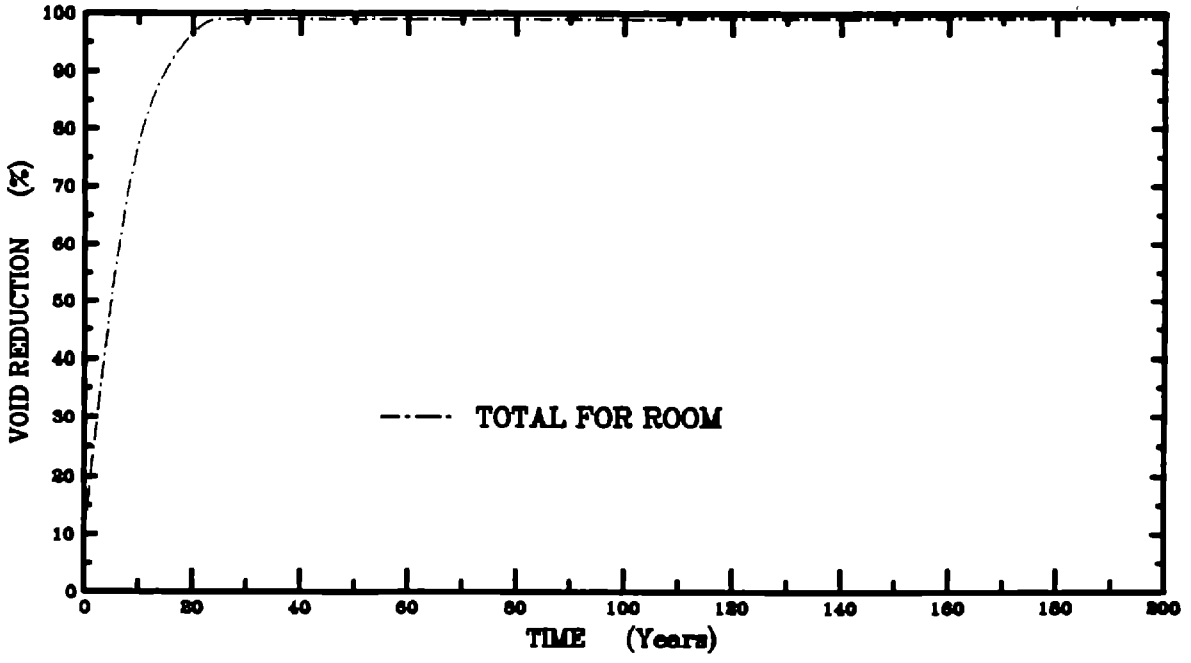

Figure 4-2. Void Reduction in the Disposal Room Filled With Crushed Salt as a Function of Time.

As illustrated in Appendix C, the average void fraction in the room decreases to 5 percent of the total room volume approximately 13 years after emplacement of the backfill. Note, however, that Weatherby [1989] used the current volume for V^o rather than the original volume. Therefore, his computed values are expected to be consistently higher than values computed using Equation 4-2 since the volume is decreasing.

The relationship between void fractions that are computed based on the initial volume and current volume can be easily developed. Equation 4-2 is written for the void fraction v_f in terms of the current volume as

$$v_f = \frac{V_v}{V^o + \Delta V} = \frac{V_v^o + \Delta V}{V^o + \Delta V} \tag{4-3}$$

From Equation 4-2, the volume change may be computed as

$$\Delta V = v_f^o V^o - V_v^o \tag{4-4}$$

The void fraction based on current volume is obtained by substituting Equation 4-4 into Equation 4-3, which gives

$$v_f = \frac{v_f^o V^o}{V^o \left(1 + v_f^o\right) - V_v^o} \tag{4-5}$$

Dividing the numerator and denominator in Equation 4-5 by the initial volume, V^o, and noting that the initial porosity is $\phi_0 = \frac{V_v^o}{V^o}$ gives

$$v_f = \frac{v_f^o}{1 + v_f^o - \phi_0} \tag{4-6}$$

When a two component backfill system such as TRU waste (superscript t) and crushed salt (superscript c) is considered, Equation 4-6 can be used to develop the void fraction equations based on the current volume. Assuming that the void fractions based on the initial volume for the TRU waste and crushed salt regions (i.e., $v_f^{t^o}$ and $v_f^{t^o}$) are known from Equation 4-2, the void fractions in the TRU waste and crushed salt based on the current volume are

$$v_f^t = \frac{v_f^{t^o}}{1 + v_f^{t^o} - \phi_0^t} \tag{4-7}$$

$$v_f^c = \frac{v_f^{c^o}}{1 + v_f^{c^o} - \phi_0^c} \tag{4-8}$$

where ϕ_0^t and ϕ_0^c are the initial porosities for the TRU waste and crushed salt regions, respectively.

The total room void fraction (superscript r) can be computed on a volume-weighted basis from the TRU waste and crushed salt void fractions based on their current volumes

$$v_f^r = \frac{v_f^t V^t + v_f^c V^c}{V^t + V^c} \tag{4-9}$$

The current volumes of the TRU waste and the crushed salt are

$$V^t = V^{t^o} + \Delta V^t \tag{4-10}$$

$$V^c = V^{c^o} + \Delta V^c \tag{4-11}$$

where

V^{c^o} = initial volume of the backfill element or region

V^{t^o} = initial volume of the waste element or region

ΔV^c = volume change of the backfill element or region

ΔV^t = volume change of the waste element or region.

From Equation 4-4, Equations 4-10 and 4-11 become

$$V^t = V^{t^o}\left(1 + v_f^{t^o}\right) - V_v^{t^o} \tag{4-12}$$

$$V^c = V^{c^o}\left(1 + v_f^{c^o}\right) - V_v^{c^o} \tag{4-13}$$

where

$V_v^{c^o}$ = initial void volume of the backfill element or region

$V_v^{t^o}$ = initial void volume of the waste element or region.

Substituting Equations 4-12 and 4-13 into Equation 4-9 gives the void fraction for the room based on the current volume of the room.

4.2 ROOM FILLED WITH CRUSHED SALT/BENTONITE

The closure of a room filled with a crushed salt/bentonite mixture (70 percent crushed salt and 30 percent bentonite by weight) was simulated for 200 years. The initial density and fully compacted or final density of the crushed salt/bentonite mixture used in this calculation was 1,478.5 kg/m^3 and 2,260 kg/m^3, respectively, which corresponds to an initial void fraction of approximately 35 percent (the same as that used for the crushed salt backfill calculations). In this simulation, the crushed salt/bentonite backfill did not consolidate sufficiently to reduce all of the voids and the fully consolidated density was not reached.

The horizontal and vertical closures of the disposal room backfilled with crushed salt are shown in Figure 4-3. The maximum horizontal and vertical closures obtained are 10 percent and 24 percent, respectively. Comparing these results with the crushed salt results in Figure 4-1 shows that the crushed salt and crushed salt/bentonite closures are nearly the same in both magnitude and rate for the first 5 years. This indicates that the room closure is primarily driven by the initial state of stress in the host rock formation and that there is little host rock — backfill interaction during the first 5 years. Thereafter, the crushed salt/bentonite backfill room closure rates become significantly less than the crushed salt backfill room closure rates until about 23 years when the crushed salt is essentially fully compacted. After 23 years, the crushed salt backfill room closure rate is close to zero and closure is virtually complete; the crushed salt/bentonite backfill room closure rate is nonzero but small and closure continues. Thus, the crushed salt/bentonite room closures accumulate slowly and approach the fully compacted, crushed salt room closures asymptotically. Since the crushed salt and crushed salt/bentonite backfilled rooms were both at the same initial void fractions, the ultimate or final state of closures of each should be the same. The comparison of closure rates between crushed salt and crushed salt/bentonite backfills may be better understood using Figures 2-1 through 2-3. These figures compare the volumetric strain rates for simple constant stress situations. The crushed salt/bentonite consolidation rates are initially greater than those of the crushed salt and eventually become significantly less which causes the crushed salt/bentonite backfill to approach full consolidation at a much slower rate than crushed salt.

The void reduction in the disposal room expressed as a percentage of the total initial void volume is shown in Figure 4-4 as a function of time. As shown in Figure 4-4, approximately 14 percent of the original void volume remains in the room after 200 years. Comparison of the crushed salt (Figure 4-2) and crushed salt/bentonite void reductions again shows the much slower rate at which the crushed salt/bentonite backfill approaches full consolidation. As illustrated in Appendix C, the average void fraction reached 5 percent after approximately 191 years.

4.3 ROOM FILLED WITH TRU WASTE AND CRUSHED SALT

The closure of a room filled with TRU waste surrounded by crushed salt was simulated for a 200-year period. The initial and fully compacted densities used in this calculation for the TRU waste were 542 kg/m^3 and 2,593 kg/m^3, respectively, corresponding to an initial void fraction of approximately 79 percent. The initial and fully compacted densities specified for the crushed salt were 1,400 kg/m^3 and 2,140 kg/m^3, respectively, corresponding to an initial void fraction of approximately 35 percent. The crushed salt was changed to a creeping material obeying the Munson-Dawson constitutive model when the volume of the crushed salt was sufficiently reduced such that all of the voids were removed and the density reached the intact density of salt. The Munson-Dawson model parameter values used are the same as

RSI-163-90-053

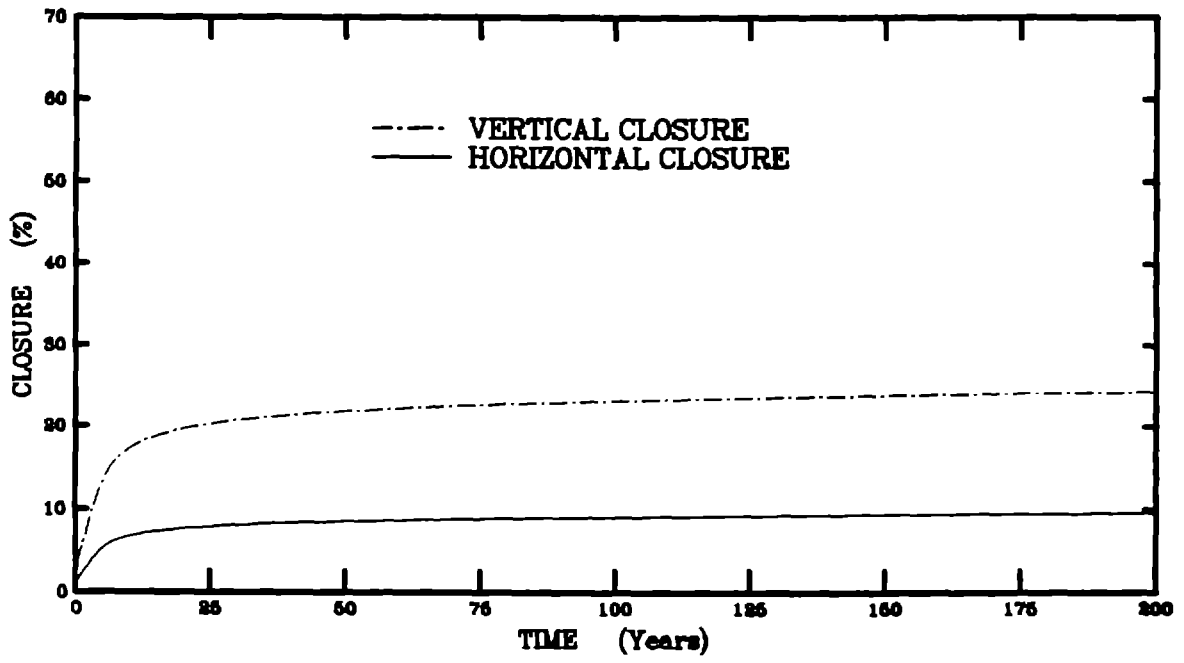

Figure 4-3. Room Closure History of a Disposal Room Filled With Crushed Salt/Bentonite.

RSI-163-90-054

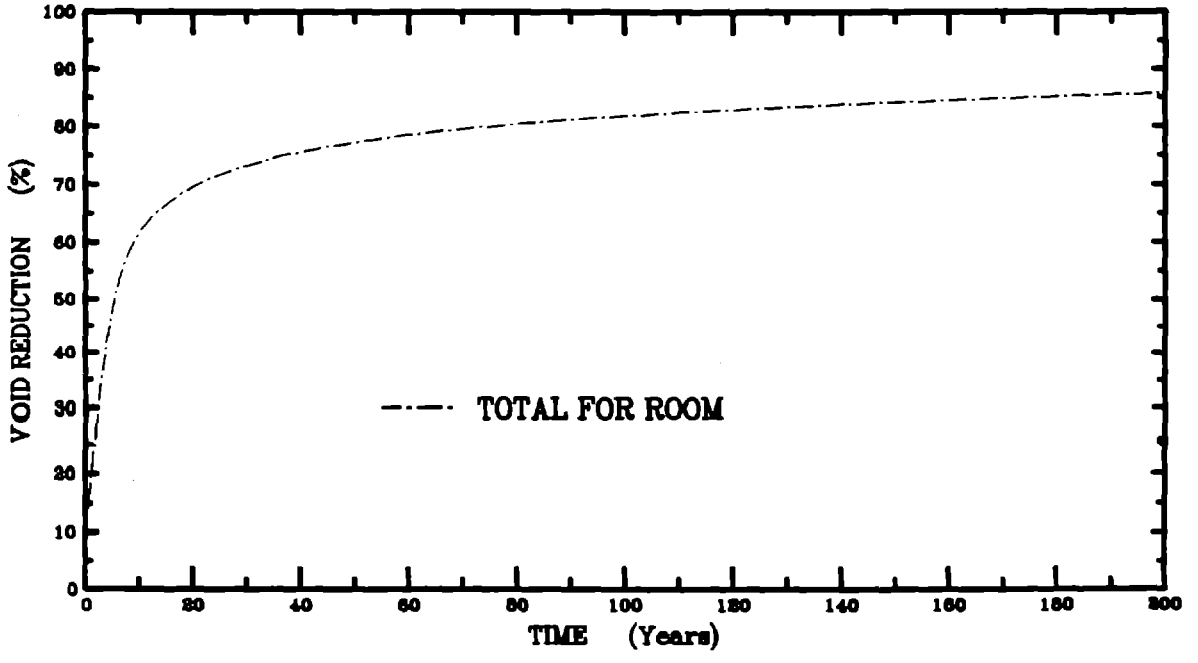

Figure 4-4. Void Reduction in the Disposal Room Filled With Crushed Salt/Bentonite as a Function of Time.

those for intact salt given in Chapter 2. Thus, following complete consolidation, the crushed salt becomes intact salt. Initially, the stiffnesses of the crushed salt and TRU waste are very low compared to the host salt formation and the initial porosity of the TRU waste is very high (79 percent) compared with the crushed salt (35 percent). Therefore, very little resistance to room closure is provided by the backfill and waste. As the crushed salt and TRU waste compact, they become stiffer and provide stabilizing forces for the underground structure and reduce the room closure rate. However, the stiffness of the TRU waste remains quite low until it is compacted to within 80 percent of its fully compacted density. Because the stiffness of the TRU waste is low, little support is provided for the crushed salt backfill, and the rate of consolidation of the crushed salt is slower than when the room is completely filled with crushed salt.

The horizontal and vertical closures of the disposal room backfilled with TRU waste and crushed salt are shown in Figure 4-5. The maximum horizontal and vertical closures obtained are 21 percent and 54 percent, respectively. Comparing these closure results with the closure results obtained for the room completely filled with crushed salt (Figure 4-1) shows that the crushed salt and crushed salt/TRU waste closures are nearly the same in both magnitude and rate for the first 5 years. This supports the earlier supposition that there is little interaction between the host rock formation and the room contents during this initial period. When the TRU waste, which has an initial void ratio of 79 percent, is present in the room, the closure rates remain large until about 50 years. At 50 years, the average void fraction in the TRU waste is about 7 percent, and the TRU waste has become stiffer and provides more resistance to room closure.

The void reduction in the waste region, backfill region, and for the entire disposal room expressed as a percentage of the total initial void volume of the respective regions are shown in Figure 4-6 as a function of time. The percent void reduction for each region was computed using Equation 4-1. Comparison of Figure 4-6 with Figure 4-2 for the crushed salt further supports the observation made above with regard to room closure rates and backfill interaction. During the simulation period, the contents of the backfilled region were changed to intact salt one element at a time upon full consolidation. During the 200 years simulated, all of the crushed salt became fully consolidated except for a small region in the corner of the room. Similarly, all the void in the waste was virtually eliminated; however, the waste required considerably more time to reach a fully compacted state. Approximately 30 years were required to reduce the void volume to 95 percent of the initial void volume for the crushed salt, while 68 years were required for the TRU waste. As shown in Figure 4-6, the combined contents of the room required approximately 60 years to reduce the void volume by 95 percent. As illustrated in Appendix C, the average void fraction reached 5 percent in the backfill region, waste region, and in the room after 15, 60, and 50 years, respectively.

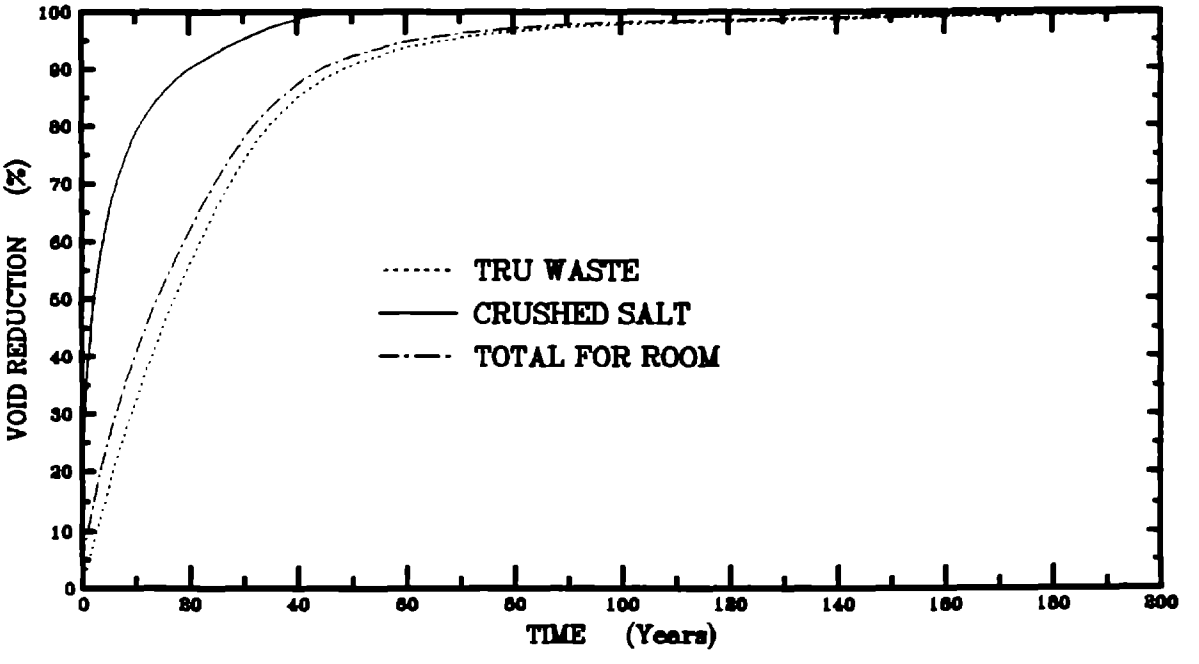

Figure 4-6. Void Reduction in the Disposal Room Filled With TRU Waste and Crushed Salt as a Function of Time.

4.4 ROOM FILLED WITH TRU WASTE AND CRUSHED SALT/BENTONITE

The closure of a room filled with TRU waste surrounded by a crushed salt/bentonite mixture was simulated for a 200-year period. The initial and fully compacted densities for the TRU waste used in this calculation were 542 kg/m^3 and 2,593 kg/m^3, respectively, corresponding to an initial void fraction of approximately 79 percent. The initial and fully compacted densities specified for the crushed salt/bentonite mixture were 1,478.5 kg/m^3 and 2,260 kg/m^3, respectively, corresponding to an initial void fraction of approximately 35 percent. During the simulation, the volume of ten crushed salt/bentonite material elements were sufficiently reduced such that all of the voids were removed and the density reached the intact density of the fully consolidated salt/bentonite mixture. For this analysis, the crushed salt/bentonite was changed to a nonlinear elastic material following complete consolidation. The elastic properties for a mixture of crushed salt and bentonite are given in Chapter 2.

The horizontal and vertical closures of the disposal room backfilled with TRU waste and crushed salt are shown in Figure 4-7. The maximum horizontal and vertical closures obtained are 18 percent and 55 percent, respectively. As discussed previously, the room closure rates and magnitudes during the initial 5-year period are essentially the same as in the other analyses. The void reduction in the waste region, backfill region, and for the entire disposal room expressed as a percentage of the total initial void volume of the respective regions are shown in Figure 4-8 as a function of time. The percent void reduction for each region was computed using Equation 4-1. During the 200 years simulated, little of the crushed salt/bentonite backfill or the TRU waste became fully consolidated. After 200 years, the initial void volume was reduced by 87 percent for the crushed salt/bentonite, 93 percent for the TRU waste. As shown in Figure 4-8, the void volume of the total combined contents of the room was ultimately reduced by 92 percent. As illustrated in Appendix C, the average void fractions in the backfill region, waste region, and in the room after 200 years are 4.4 percent, 5.4 percent, and 5.1 percent, respectively.

4.5 ROOM FILLED WITH VITRIFIED WASTE AND CRUSHED SALT

The closure of a room filled with vitrified waste surrounded by crushed salt was analyzed assuming an initial density for the crushed salt to be 65 percent of the density of intact salt. The initial and fully compacted densities specified for the crushed salt were 1,400 kg/m^3 and 2,140 kg/m^3, respectively. This corresponds to an initial void fraction of approximately 35 percent. The vitrified waste was modeled as a linearly elastic material as described in Chapter 2. In this simulation, the crushed salt backfill consolidated sufficiently to remove all of the voids, and the density of the crushed salt reached the intact density of salt. At this point in the simulation, the crushed salt was changed to a creeping material obeying the

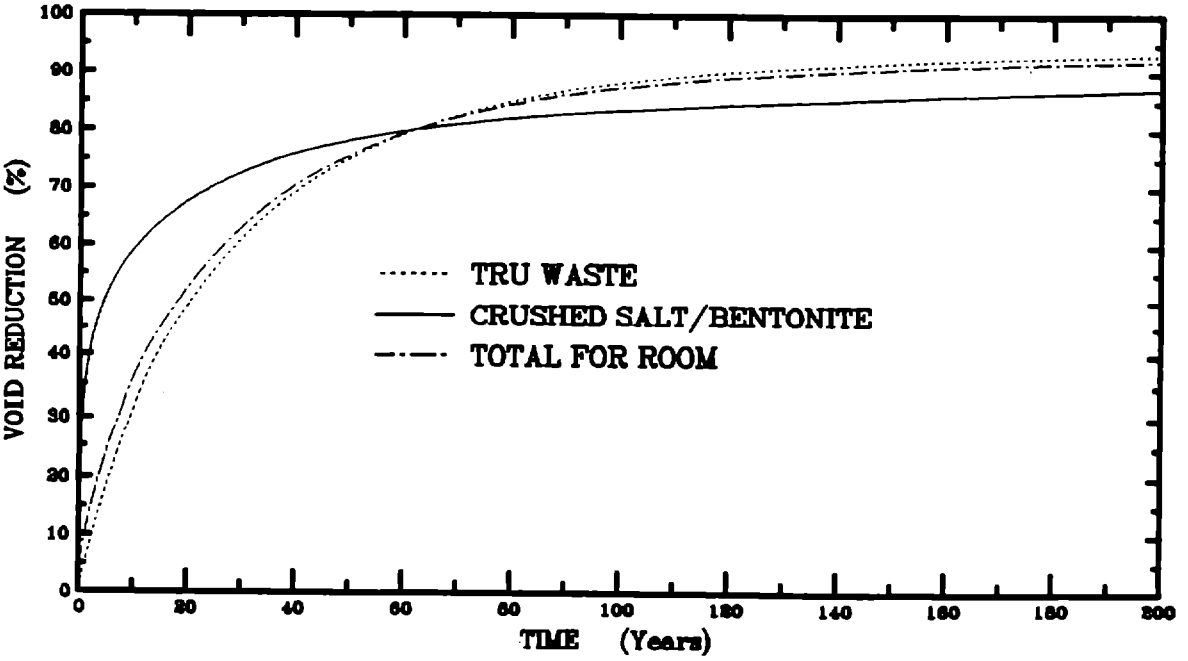

Figure 4-8. Void Reduction in the Disposal Room Filled With TRU Waste and Crushed Salt/Bentonite as a Function of Time.

Munson-Dawson constitutive model. The Munson-Dawson model parameter values used are the same as those given for intact salt in Chapter 2.

The horizontal and vertical closures of the disposal room backfilled with vitrified waste and crushed salt are shown in Figure 4-9. The maximum horizontal and vertical closures obtained are 2.4 percent and 9.4 percent, respectively. These closures are substantially less than the other cases examined which illustrates the effect of a stiff TRU waste component with zero initial porosity. In this case, with the stiff TRU waste component, the waste and backfill interact with the host rock formation earlier in time. Comparing Figure 4-9 with the closure results from the other analyses shows that the vitrified waste and backfill have little effect on the host rock deformation for approximately 1 year; whereas, the other cases show little impact for approximately 5 years. The stiffness of the vitrified waste provides the mechanism for more rapid consolidation of the surrounding crushed salt backfill and subsequent back pressure on the host formation, which slows the rate of deformation and reduces the overall magnitude of room closure. As shown in Figure 4-10, 95 percent of the void in the region filled with crushed salt is eliminated after 13 years. As illustrated in Appendix C, the average void fraction reaches 5 percent in the backfill region within 6 years.

4.6 ROOM FILLED WITH CRUSHED SALT AND SHREDDED METAL MIXED WITH CRUSHED SALT

The closure of a room filled with shredded metallic waste mixed with crushed salt was analyzed assuming the mixture contained 80 percent crushed salt and 20 percent metallic waste by volume. The shredded metal/crushed salt mixture was surrounded on all sides by crushed salt. The initial and fully compacted densities specified for the crushed salt were 1,400 kg/m^3 and 2,140 kg/m^3, respectively. This corresponds to an initial void fraction of approximately 35 percent. The initial and fully compacted densities specified for the crushed salt/shredded metal mixture were 2,689 kg/m^3 and 3,717 kg/m^3, respectively. This corresponds to an initial void fraction of approximately 28 percent. During the simulation, the shredded metal/crushed salt mixture and the crushed salt backfill consolidated sufficiently to remove all of the voids. When the crushed salt and shredded metal/crushed salt elements attained their respective intact densities, the elements were changed to a creeping material obeying the Munson-Dawson constitutive model. The Munson-Dawson model parameter values used are the same as those given for intact salt in Chapter 2.

RSI-163-90-059

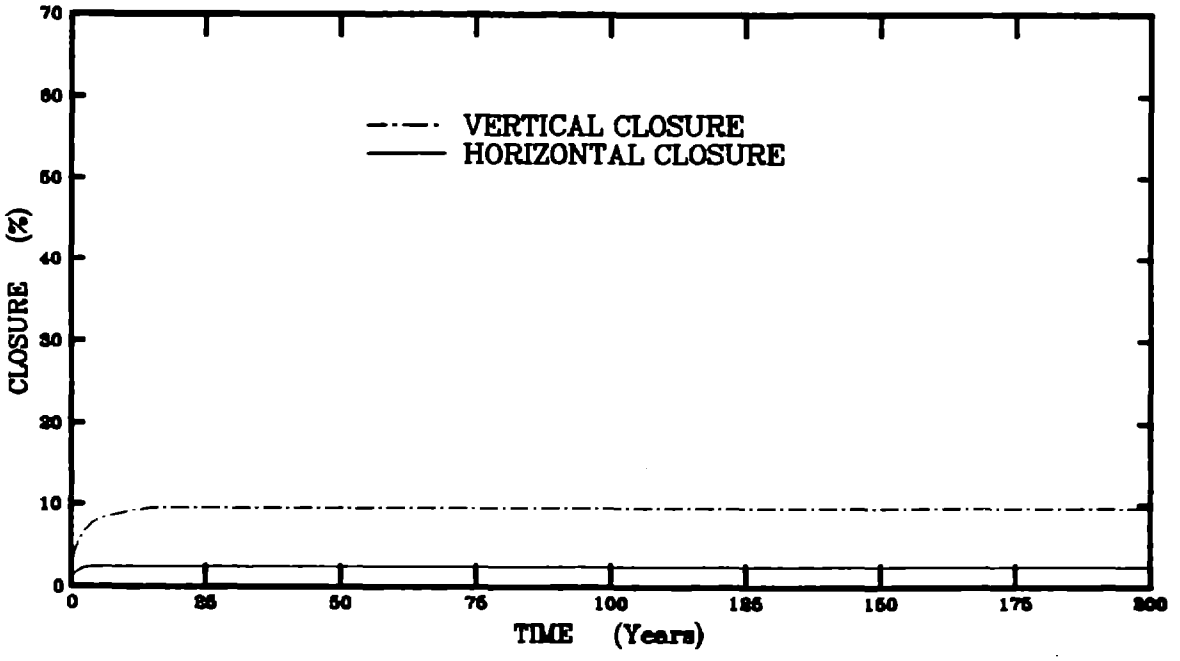

Figure 4-9. Room Closure History of a Disposal Room Filled With Vitrified Waste and Crushed Salt.

RSI-163-90-060

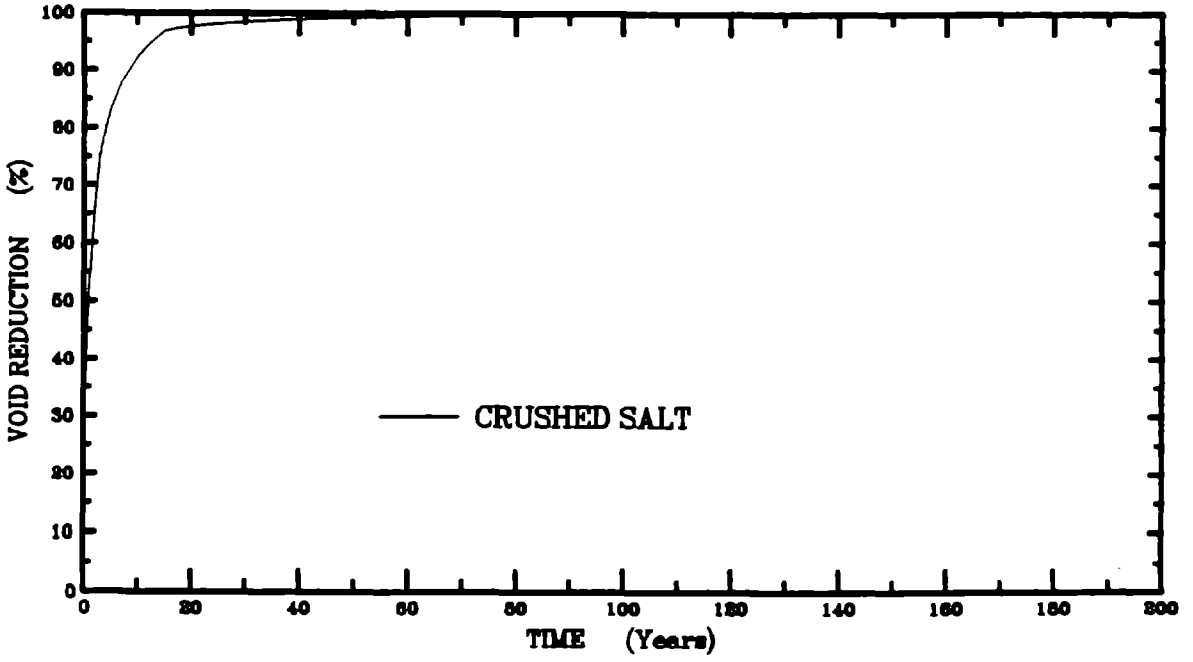

Figure 4-10. Void Reduction in the Disposal Room Filled With Vitrified Waste and Crushed Salt as a Function of Time.

The horizontal and vertical closures of the disposal room backfilled with shredded metal/crushed salt and crushed salt are shown in Figure 4-11. The maximum horizontal and vertical closures obtained are 9.6 percent and 24.2 percent, respectively. Comparison of these room closure results with those for crushed salt (Figure 4-1) shows identical behavior during the initial period with the final closures being less for the shredded metal/crushed salt mixture. Combining the shredded metal waste with the crushed salt includes two items that effect the room closure: (1) the initial porosity of the shredded metal/crushed salt mixture is less than that of the pure crushed salt and (2) the shredded metal/crushed salt mixture becomes a stiffer structural member than the pure crushed salt upon compaction. These two items result in less room closure and faster consolidation of the crushed salt backfill covering the shredded metal/crushed salt mixture.

The void reduction in the waste region, backfill region, and for the entire disposal room expressed as a percentage of the total initial void volume of the respective regions are shown in Figure 4-12 as a function of time. The percent void reduction for each region was computed using Equation 4-1. Approximately 16 years were required to reduce the void volume to 95 percent of the initial void volume for the crushed salt, while 11 years were required for the shredded metal/crushed salt mixture. As shown in Figure 4-12, the combined contents of the room required 12 years to reduce the void volume by 95 percent of the initial void volume. As illustrated in Appendix C, the average void fraction in the backfill region, waste region, and in the room reach 5 percent after approximately 11 years.

5.0 SUMMARY AND CONCLUSIONS

Constitutive relations were developed and modified to simulate the backfill and host rock formation for disposal room configuration at WIPP including viscoplastic (creep), nonlinear elastic, creep consolidation, and nonlinear elastic and consolidation mixture models. These constitutive models were incorporated into the finite element computer code SPECTROM-32. The TRU waste model contains major uncertainties and assumptions that could significantly affect the results obtained. Weaknesses exist for the crushed salt constitutive model particularly with respect to its deviatoric response. The volumetric behavior of the backfill is based on hydrostatic laboratory tests, but the deviatoric response included is hypothetical. Further testing and analysis of crushed salt is required to guide the development of its constitutive model. The completed development effort provides a calculational support tool to investigate operational and performance questions relevant to the WIPP disposal room waste isolation strategies.

Different WIPP disposal room backfill configurations were examined for a simulation period of 200 years. Room contents investigated include crushed salt, a crushed salt/bentonite mixture, crushed salt covering TRU waste, crushed salt/bentonite covering TRU waste, crushed salt covering a mixture of crushed salt and shredded metallic waste, and crushed salt covering a vitrified waste. The results show that disposal room contents do not significantly affect room closure during the initial 5-year period. This is illustrated in Figures 5-1 and 5-2, which include plots of the vertical and horizontal room closure histories, respectively, for each of the cases analyzed. The one exception is the stiff, nonporous vitrified waste, which provides resistance to room deformation very early in time.

In most cases, the average void fractions became less than 5 percent within 200 years although the time required to obtain these reduced void fraction values varies significantly for the different backfill configurations. In this case, the void fraction values are computed using the initial void volume of the region as given by Equation 4-2. The one case that did not attain an average void fraction less than 5 percent is the crushed salt/bentonite mixture covering TRU waste, which reached a value of 5.09 percent after 200 years. Table 5-1 gives the time required for the average void fractions in the room, TRU waste, and surrounding backfill material to reach a value of 5 percent, and the time required for the average void fraction in the room (i.e., room refers to and includes all room contents) to reach a value of 0.5 percent. At an average void fraction of 0.5 percent, the room contents, including waste and backfill, are essentially fully compacted.

The results given in Table 5-1 are consistent with the room contents. When a stiff material is covered with crushed salt as in the case of the vitrified waste, the crushed salt compacts rapidly since the vitrified waste deforms little and the room deformation is absorbed almost entirely by the crushed salt backfill. Conversely, the TRU waste packages have initial void ratios much higher than the crushed salt and

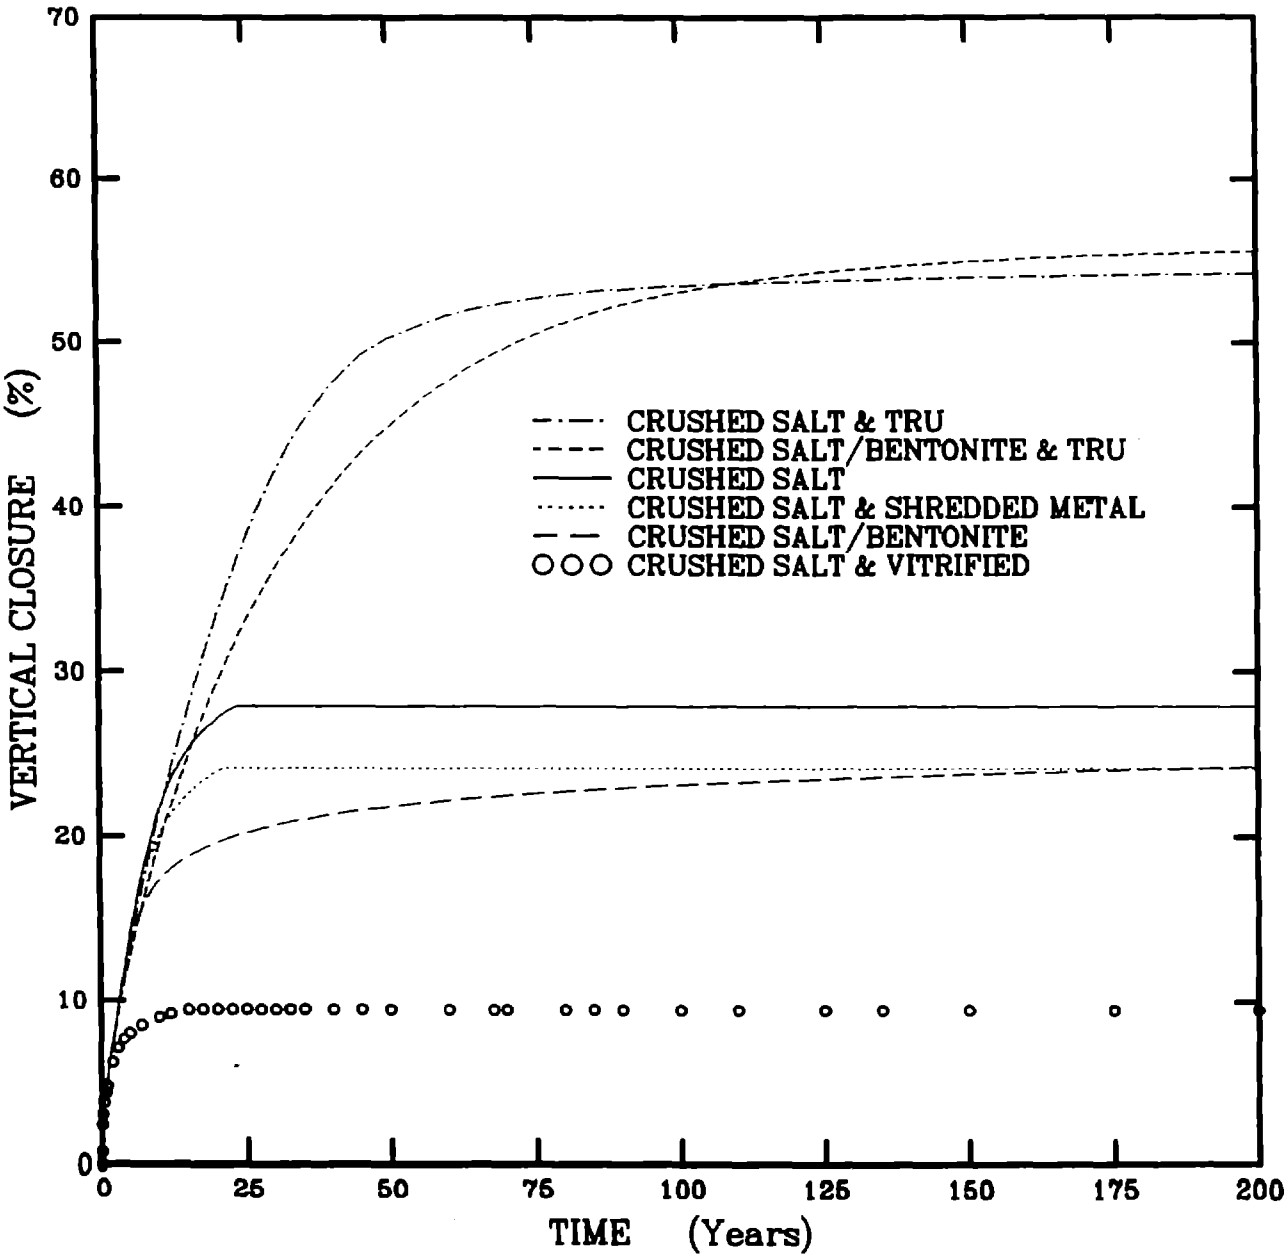

Figure 5-1. Comparisons of Vertical Closure Histories for Different Room Emplacement Scenarios.

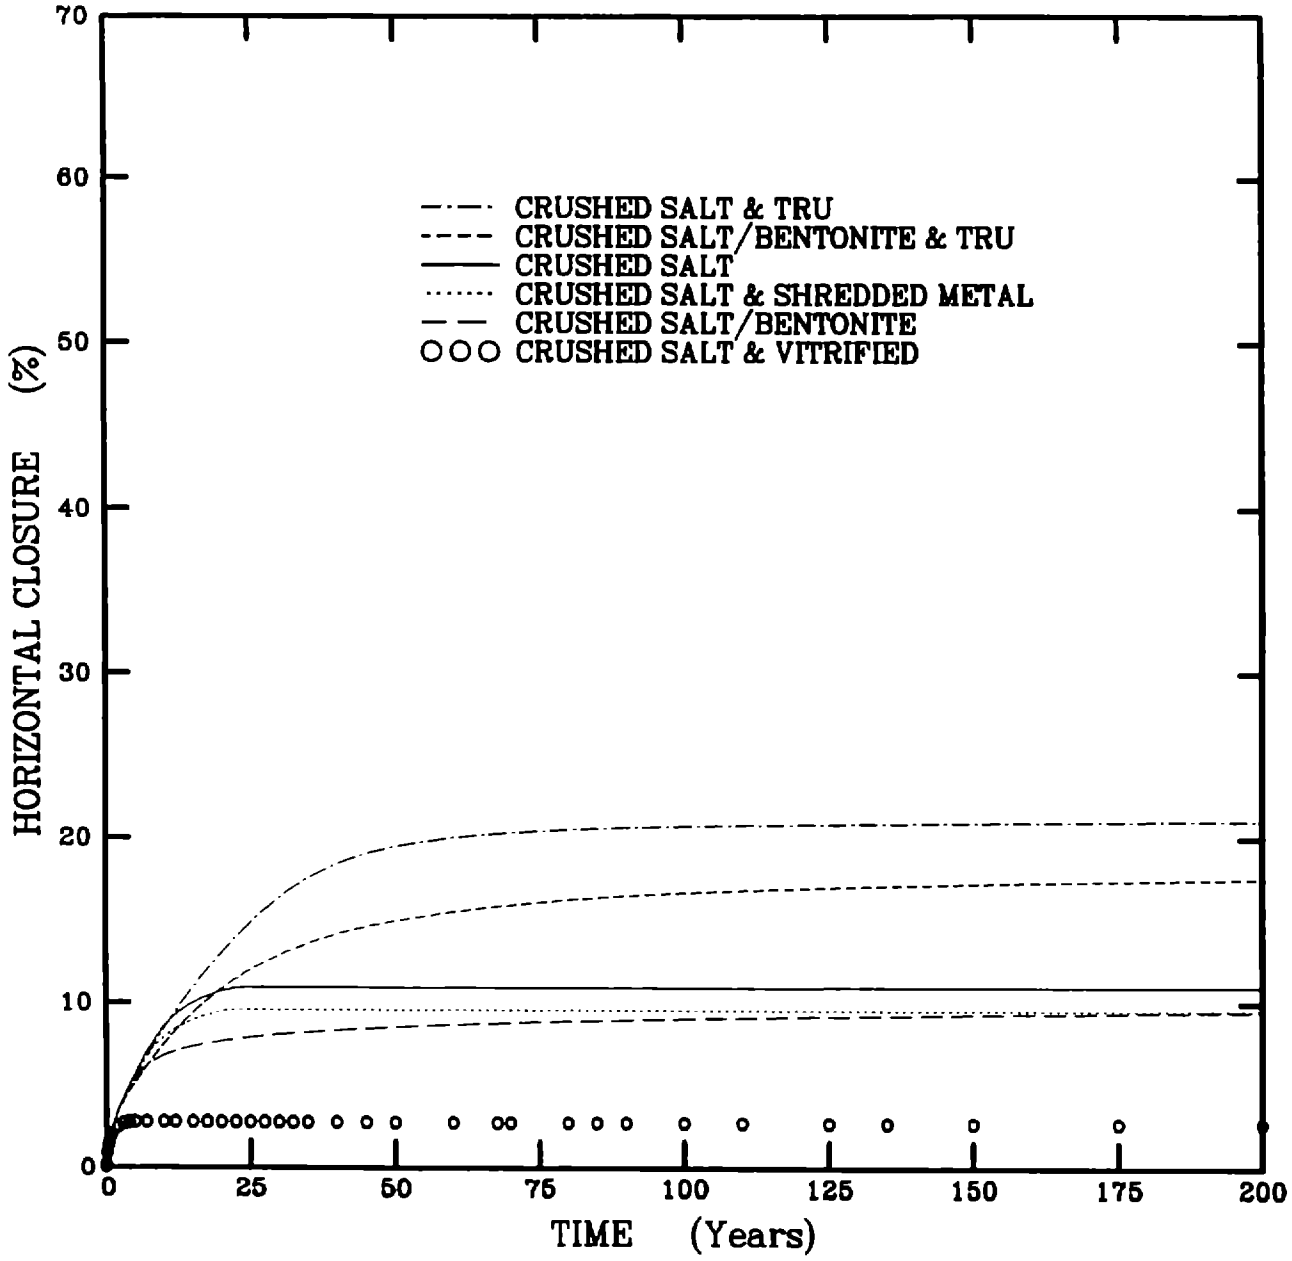

Figure 5-2. Comparisons of Horizontal Closure Histories for Different Room Emplacement Scenarios.

are significantly softer until the TRU waste is compacted significantly. Therefore, when TRU waste is included in the room, most of the room deformation is absorbed by the soft TRU waste resulting in longer times to attain reduced void fractions. When crushed salt/bentonite mixtures are assumed to be the backfill material, the consolidation rate is reduced and the times shown in Table 5-1 are significantly greater. However, as discussed in Chapter 2, the creep consolidation parameter values for crushed salt/bentonite mixtures are based on only three tests. Further testing on crushed salt/bentonite mixtures may provide information that will have a significant impact on these results.

Table 5-1. Average Void Fraction Comparisons for the Analyses

Analysis	Time to Reach Void Fraction Value (Yr)			
	5 Percent			0.5 Percent
	Room	Waste	Backfill	Room
Crushed Salt	12.7	NA[a]	12.7	22.8
Crushed Salt/Bentonite	191.2	NA	191.2	>200
Crushed Salt and TRU Waste	59.7	49.7	14.8	166.3
Crushed Salt/Bentonite and TRU Waste	200[b]	—[c]	146.8	>200
Crushed Salt and Crushed Salt/Shredded Metal Mixture	10.2	9.9	10.6	19.4
Crushed Salt/Vitrified Waste	1.3	NA	6.0	13.5

(*a*) Not applicable.
(*b*) Actual value was 5.09 percent at 200 years.
(*c*) Value was 5.4 percent at 200 years.

Results from SPECTROM-32 and SANCHO are compared for backfilled disposal room problems with crushed salt and crushed salt-bentonite (Appendix B). The calculated deformations and stresses from the two analyses agree reasonably well despite differences in methodology such as the consolidation model, intact salt creep model, finite strain, and material properties.

6.0 NOMENCLATURE

A = creep consolidation material parameter $[m^3/kg]$

A_1 = Munson-Dawson material parameter $[s^{-1}]$

A_2 = Munson-Dawson material parameter $[s^{-1}]$

B_0 = creep consolidation material parameter $[\frac{kg}{m^3 \cdot s}]$

B_1 = creep consolidation material parameter $[\text{MPa}^{-1}]$

$\hat{B}_1$ = Munson-Dawson material parameter $[s^{-1}]$

B_2 = Munson-Dawson material parameter $[s^{-1}]$

c = Munson-Dawson material parameter $[K^{-1}]$

C_{ijkl} = compliance tensor $[\text{MPa}^{-1}]$

E = Young's modulus [MPa]

$\{f\}$ = load vector [MN]

F = Munson-Dawson transient function

G = shear modulus [MPa]

G^f = fully compacted mixture shear modulus [MPa]

G_f = solid (intact) shear modulus [MPa]

G_m = inert material shear modulus [MPa]

G_s = crushed salt shear modulus [MPa]

G_0 = nonlinear elastic shear modulus material constant [MPa]

G_1 = nonlinear elastic shear modulus material constant $[m^3/kg]$

$H(.)$ = Heaviside step function

J_2 = second invariant of deviator stress $[\text{MPa}^2]$

J_3 = third invariant of deviator stress $[\text{MPa}^3]$

K = bulk modulus [MPa]

K^f = fully compacted mixture bulk modulus [MPa]

K_f = solid (intact) bulk modulus [MPa]

K_m = inert material bulk modulus [MPa]

K_o = Munson-Dawson material parameter

K_s = crushed salt bulk modulus [MPa]

$[K_t]$ = tangent stiffness matrix [MPa]

K_0 = nonlinear elastic bulk modulus material constant [MPa]

K_1 = nonlinear elastic bulk modulus material constant $[m^3/kg]$

m = Munson-Dawson material parameter

m_s = mass fraction of salt

m_m = mass fraction of inert material

M = total mass [kg]

M_m = inert material mass [kg]

M_s = crushed salt mass [kg]

n_1 = Munson-Dawson material parameter

n_2 = Munson-Dawson material parameter

q = Munson-Dawson activation volume

Q_1 = Munson-Dawson activation energy [cal/mol]

Q_2 = Munson-Dawson activation energy [cal/mol]

R = universal gas constant $[\frac{cal}{mol-K}]$

S_{ij} = deviatoric stress tensor [MPa]

t_{ij} = square of the deviator of the reduced stress [MPa^2]

u = displacement [m]

T = temperature $[K]$

v = void reduction

v^f = fully compacted volume fraction of a mixture

v_f = void fraction based on current volume

v_f^o = void fraction based on initial volume

v_f^c = void fraction for backfill region based on current volume

$v_f^{c^o}$ = void fraction for backfill region based on initial volume

v_f^t = void fraction for waste region based on current volume

$v_f^{t^o}$ = void fraction for waste region based on initial volume

v_f^r = void fraction for room region based on current volume

v_{is} = volume fraction of solid salt in crushed salt

v_{is}^f = fully compacted volume fraction of solid salt in crushed salt

v_m = volume fraction of inert material

v_m^f = fully compacted volume fraction of inert material

v_s = volume fraction of crushed salt

v_0^s = initial volume fraction of crushed salt

V = total volume $[m^3]$

V^o = initial volume $[m^3]$

V_{is} = solid salt volume within crushed salt $[m^3]$

V_m = inert material volume $[m^3]$

V_s = crushed salt volume $[m^3]$

V^c = volume of backfill region $[m^3]$

V^{c^o} = initial volume of backfill region $[m^3]$

$V_v^{c^o}$ = initial void volume of backfill region $[m^3]$

V^f = fully compacted mixture volume $[m^3]$

V_s^f = fully compacted crushed salt volume $[m^3]$

V^t = volume of waste region $[m^3]$

V^{t^o} = initial volume of waste region $[m^3]$

$V_v^{t^o}$ = initial void volume of waste region $[m^3]$

V_v = void volume $[m^3]$

V_v^o = initial void volume $[m^3]$

α = Munson-Dawson material parameter

β = Munson-Dawson material parameter

δ = Munson-Dawson recovery parameter

δ_{ij} = Kronecker delta

Δ = Munson-Dawson workhardening parameter

Δf = incremental load [MPa]

Δu = incremental displacement $[m]$

ΔV = volume change $[m^3]$

ΔV^c = volume change in backfill region $[m^3]$

ΔV^t = volume change in waste region $[m^3]$

ϵ_s = steady-state strain

ϵ_v = total volumetric strain

ϵ_{vs} = total volumetric strain of crushed salt in a mixture

ϵ_{s_1} = steady-state strain for dislocation climb

ϵ_{s_2} = steady-state strain from an undefined mechanism

ϵ_{s_3} = steady-state strain for glide

ϵ_e^c = invariant creep strain measure

ϵ_t^f = Munson-Dawson transient strain limit

ϵ_v^c = inelastic volumetric strain

ϵ_{vs}^c = inelastic volumetric strain of crushed salt in a mixture

ϵ_{ij} = total strain tensor

ϵ_{ij}^c = creep strain tensor

ϵ_{ij}^e = elastic strain tensor

$\epsilon_{eq_1}^c$ = equivalent inelastic shear strain measure

$\epsilon_{eq_2}^c$ = equivalent inelastic shear strain measure

ς = Munson-Dawson internal variable

η = empirical constant for creep consolidation model

Θ = generic property of a mixture

θ = frictional material parameter in creep flow potential (dimensionless for pressure-dependent, degrees for frictional)

θ_i = generic property of ith material in a mixture

κ = material constant in nonlinear TRU waste model [MPa^{-1}]

λ = material constant in nonlinear TRU waste model [MPa^{-1}]

μ = Munson-Dawson material parameter [MPa]

ν = Poisson's Ratio

ρ = density [kg/m^3]

ρ^f = fully compacted mixture density [kg/m^3]

ρ_f = final or intact material density [kg/m^3]

ρ_m = inert material density [kg/m^3]

ρ_{is} = solid salt density within crushed salt [kg/m^3]

ρ_s = crushed salt density $[kg/m^3]$

ρ_0 = initial material density $[kg/m^3]$

ρ_0^s = initial crushed salt density $[kg/m^3]$

σ_a = axial stress [MPa]

σ_e = invariant stress measure [MPa]

σ_m = mean stress [MPa]

σ_0 = Munson-Dawson cut-off stress [MPa]

σ_e^f = invariant stress measure [MPa]

$\sigma_{eq_1}^f$ = invariant stress measure [MPa]

$\sigma_{eq_2}^f$ = invariant stress measure [MPa]

σ_{ij} = stress tensor [MPa]

τ = flow dilatancy material parameter in creep flow potential (dimensionless for pressure-dependent, degrees for frictional)

ϕ = porosity

ϕ_s = crushed salt porosity

ϕ_0 = initial porosity

ϕ_0^c = initial porosity of backfill region

ϕ_0^t = initial porosity of waste region

ψ = Lode angle [degrees]

$\dot{\chi}$ = time rate of change of variable χ $[s^{-1}]$

σ_{kk} = repeated indices imply summation ($\sigma_{kk} = \sigma_{11} + \sigma_{22} + \sigma_{33}$)

APPENDIX B
COMPARISON OF SPECTROM-32 AND SANCHO RESULTS

B.1 INTRODUCTION

The purpose of Appendix B is to compare results obtained using SPECTROM-32 and presented in this report to those obtained using SANCHO [Weatherby, 1989 and Weatherby and Brown, 1990] for those types of problems common between the different analyses. Fundamental differences between the analyses are discussed in the next section before these results are presented.

B.2 DIFFERENCES BETWEEN ANALYSES

Several differences exist between the methods used to analyze the backfilled disposal rooms. The two most significant differences relate to the constitutive relations used for the various materials and the finite-strain formulation in SANCHO versus the small-strain formulation in SPECTROM-32. The following sections elaborate on the differences between the analyses.

B.2.1 Basic Problem Parameters

The basic problem parameters consist of the room and pillar geometry, depth of the room, mesh refinement of the modeled region, temperature, and boundary conditions. The same basic problem parameters were used for all SPECTROM-32 analyses, and except for a variation in the mesh refinement, the basic problem parameters in the SPECTROM-32 analyses are identical to the crushed-salt backfill and crushed-salt/TRU waste SANCHO analyses presented by Weatherby [1989]. However, the crushed salt/bentonite backfill analysis presented by Weatherby and Brown [1990] differs from the other analyses in two ways: (1) the total mesh height was 54 m rather than 27 m and (2) the overburden pressure was 14.8 MPa rather than 14.3 MPa as shown in Figure 3-1. The mesh refinement used for the SPECTROM-32 analyses is shown in Figure 3-1 and does not vary significantly from that used by SANCHO for the crushed-salt backfill and crushed-salt/TRU waste analyses.

B.2.2 Crushed Salt Model and Material Constants

The crushed-salt consolidation volumetric response model used in both analyses was developed by Sjaardema and Krieg [1987]. Although the nonlinear elastic component of the crushed salt consolidation model was the same in the SPECTROM-32 and SANCHO analyses, corresponding elastic material constants for crushed salt used in the SANCHO analyses were reduced by a factor of 12.5 [Weatherby, 1989]. This reduction in elastic properties stems from a recommendation by Morgan [1987]

that is based on the usage of the early version of the reference constitutive relation for salt creep (i.e., WIPP secondary creep law) that produced good agreement between calculated and measured deformations of WIPP field experiments. Table B-1 gives the nonlinear elastic model for crushed salt along with the respective parameters values used in the two analyses. Note that volumetric compaction is taken to be negative.

Table B-1. Nonlinear Elastic Model and Material Parameters for Crushed Salt

Parameter	Units	Value (SPECTROM-32 Analyses)	Value (SANCHO Analyses)
K_0	MPa	0.01760	0.00141
K_1	m^3/kg	0.00653	0.00653
G_0	MPa	0.01060	0.000864
G_1	m^3/kg	0.00653	0.00653
K_f	MPa	20,626	1,653
G_f	MPa	12,423	1,013
ρ_0	kg/m^3	1,400	1,400
ρ_f	kg/m^3	2,140	2,140

$$K = K_0 e^{\frac{K_1 \rho_0}{1+\epsilon_v}}$$

$$G = G_0 e^{\frac{G_1 \rho_0}{1+\epsilon_v}}$$

where ϵ_v = total volumetric strain

$$\rho_0 = \rho\,(1 + \epsilon_v)$$

Note: If $K > K_f$, then $K = K_f$ and $G = G_f$

If $G > G_f$, then $G = G_f$ and $K = K_f$

The volumetric creep consolidation component of the crushed salt model is essentially the same for the SANCHO and SPECTROM-32 analyses. The crushed salt consolidation model developed by Sjaardema and Krieg [1987] given in Chapter 2 was implemented into SANCHO [Weatherby, 1989] and SPECTROM-32 [Callahan, 1990]. The volumetric creep consolidation model parameters values used in the two analyses were identical and are given in Table 2-3 for crushed salt and Table 2-5 for the crushed salt/bentonite mixture.

A deviatoric component was added to the creep consolidation model used in SPECTROM-32. Volumetric-only models are deficient because they produce unrealistic results. For example, a cylinder subjected to uniaxial compression will

also compact laterally since the cylinder has a mean stress component. As discussed in Chapter 2, a deviatoric component was arbitrarily developed to offset the lateral strain components generated under uniaxial loading. A more complex deviatoric component is difficult to justify since, until recently, laboratory data for creep consolidation were limited to tests conducted under hydrostatic loading. SANCHO used a form of the WIPP secondary creep law for intact salt as modified by Sjaardema and Krieg [1987] for the deviatoric response of the crushed salt.

B.2.3 Intact Salt Model

Recently, a new WIPP reference constitutive relation for intact salt creep was proposed [Munson, 1989]. The original baseline WIPP constitutive relation (secondary creep law) along with a Mises-type flow potential was used in the SANCHO analyses. The Munson-Dawson constitutive relation (see Chapter 2) along with a Tresca flow potential was used in the SPECTROM-32 analyses to describe the intact salt behavior. This combination was recommended by Munson [1989] because of favorable results from a previous study [Munson et al., 1989].

Similar to the crushed salt, the elastic properties of intact salt recommended by Munson [1989] were reduced by a factor of 12.5 for the SANCHO analyses. The SPECTROM-32 analyses did not use reduced elastic constants. Note that in both sets of analyses, the crushed salt elastic constants approach the intact salt elastic constants as the crushed salt becomes fully consolidated; however, the properties in the SANCHO analyses were modified by the 12.5 reduction factor.

B.2.4 TRU Waste Model

The SPECTROM-32 analyses used the nonlinear elastic material model developed in Section 2.4 for the TRU waste; whereas, SANCHO used a volumetric plasticity model.

B.3 COMPARISON OF RESULTS

Three common analyses performed using SPECTROM-32 and SANCHO exist for comparison:

1. Room completely backfilled with crushed salt.
2. Room completely backfilled with crushed salt/bentonite.
3. Room containing TRU waste covered with crushed salt.

The SANCHO results for each of these analyses were obtained by digitizing the graphical information presented in Weatherby [1989] and Weatherby and Brown [1990]. Figures B-1 through B-6 compare the room closure and average void fraction results obtained for the room simulations using SANCHO and SPECTROM-32.

Figure B-1 compares the room closure results and Figure B-2 compares the average void fraction for the two analyses of the room backfilled completely with crushed salt. The SPECTROM-32 results show faster room closure than SANCHO and consequently a shorter time to fully consolidate the backfill. Figures B-3 and B-4 show the same results for the crushed salt/bentonite backfill analysis. Despite the differences between the SPECTROM-32 and SANCHO analyses, the crushed salt/bentonite backfill analyses results compare extremely well. Figures B-5 and B-6 illustrate the comparison of the room closures and average void fractions obtained for the TRU waste covered with crushed salt.

Figure B-5. Comparison of Room Closures for a Room Containing TRU Waste and Crushed Salt.

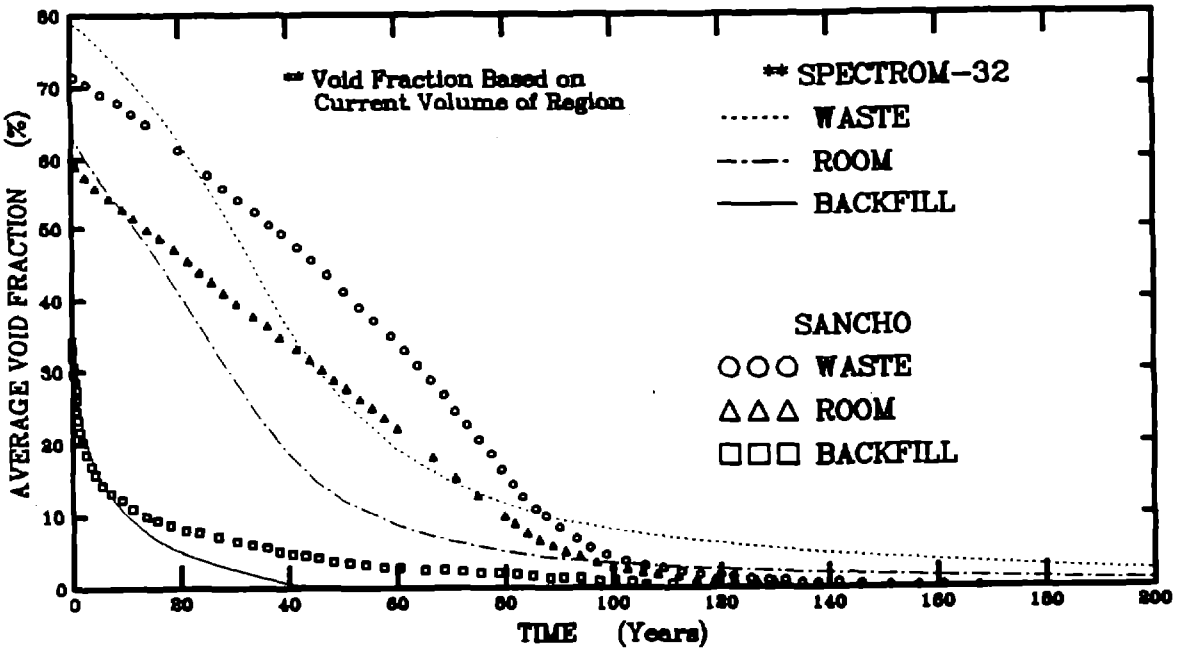

Figure B-6. Comparison of the Average Void Fractions in a Room Containing TRU Waste and Crushed Salt (Current Volume).

The results obtained from the TRU waste problem (Figures B-5 and B-6) are somewhat similar but do not compare as well as the two previously discussed analyses. An important component in this analysis is the TRU waste, and the constitutive models used in SPECTROM-32 and SANCHO for TRU waste are considerably different. Thus, the difference in the TRU waste model is thought to be the primary reason for the larger discrepancies between the two solutions.

APPENDIX C
AVERAGE VOID FRACTION AND MEAN STRESS RESULTS

C.1 SUMMARY

Appendix C includes average void fraction and mean stress results for the six cases investigated in Figures C-1 through C-6 and Figures C-7 through C-12, respectively. The average void fractions shown are computed using Equation 4-2, which is based on the initial volume of the region considered. When more than one component is included in a storage room, the average void fractions for each of the components are shown. For example, the case involving crushed salt and TRU waste room contents, with results shown in Figure C-3, includes three curves — one curve each for the TRU waste, crushed salt, and room. Each of these curves was computed using Equation 4-2 with the void volume and initial volume representing the specific region of interest. The curve labeled *Room* represents the average void fraction of the combined waste and backfill in the room (i.e., total room contents). The average void fraction for the room is computed by weighting the average void fractions in the waste and the backfill according to their respective volumes and dividing by the initial volume of the room.

Figures C-7 through C-12 illustrate the mean stress at three distinct locations in the room. These three locations are labeled *Center*, *Roof*, and *Rib*. *Center* refers to the center of the room with mean stress results taken from the element nearest the center of the room. *Roof* refers to the center of the room near the roof with mean stress results taken from the backfill element nearest the center of the room at the intact salt/backfill interface along the roof. *Rib* refers to the midheight of the room near the rib with mean stress results taken from the backfill element nearest the midheight of the room at the intact salt/backfill interface along the rib.

Crushed Salt Constitutive Model

G.D. Callahan
RESPEC
Rapid City, SD 57709-0725

Sandia Contract No. AG4911

ABSTRACT

The constitutive model used to describe the deformation of crushed salt is presented in this report. Two mechanisms X dislocation creep and grain boundary diffusional pressure solution X are combined to form the basis for the constitutive model governing the deformation of crushed salt. The constitutive model is generalized to represent three-dimensional states of stress. Upon complete consolidation, the crushed-salt model reproduces the Multimechanism Deformation (M-D) model typically used for the Waste Isolation Pilot Plant (WIPP) host geological formation salt. New shear consolidation tests are combined with an existing database that includes hydrostatic consolidation and shear consolidation tests conducted on WIPP and southeastern New Mexico salt. Nonlinear least-squares model fitting to the database produced two sets of material parameter values for the model X one for the shear consolidation tests and one for a combination of the shear and hydrostatic consolidation tests. Using the parameter values determined from the fitted database, the constitutive model is validated against constant strain-rate tests. Shaft seal problems are analyzed to demonstrate model-predicted consolidation of the shaft seal crushed-salt component. Based on the fitting statistics, the ability of the model to predict the test data, and the ability of the model to predict load paths and test data outside of the fitted database, the model appears to capture the creep consolidation behavior of crushed salt reasonably well.

ACKNOWLEDGMENTS

The author is grateful for the encouragement, support, insight, and constructive criticism received from Dr. Frank D. Hansen of Sandia National Laboratories during the development of this model for crushed salt. The author is appreciative and acknowledges the assistance of Dr. Marc C. Loken in the model fitting effort and the assistance of Mr. Kerry L. DeVries in conducting the shaft seal simulations. The work was funded by Sandia National Laboratories under Sandia contract AG-4911.

1.0 INTRODUCTION

1.1 BACKGROUND

Construction of the Waste Isolation Pilot Plant (WIPP) was initiated by the U.S. Department of Energy (DOE) in 1981 to develop the technology for the safe management, storage, and disposal of transuranic (TRU) radioactive wastes generated by the DOE defense programs. The WIPP, located in southeastern New Mexico at a depth of approximately 655 meters in bedded halites, is designed to be a full-scale geologic repository. Access to the facility is provided through vertical shafts. Since these shafts provide direct communication from the underground facilities through the upper lithologic units to the surface, they will be sealed to limit fluid flow into the repository and to prevent hazardous materials from migrating out of the repository. The U.S. Environmental Protection Agency (EPA) has determined that the WIPP can safely contain transuranic waste and that it will comply with EPA's radioactive waste disposal standards.

Crushed salt has been selected as one of the primary seal components for permanent sealing of the WIPP underground openings. Crushed salt's desirable characteristics include chemical compatibility, eventual mechanical similarity with the host salt formation, and ready availability from site excavation. Laboratory tests have shown that crushed salt achieves desirable permeability characteristics as consolidation increases the material density. In addition, voids and fractures close and heal in salt in response to applied loads. After sufficient time, loading of the crushed salt resulting from creep closure of the shaft will form a long-term seal component from the reconsolidated crushed salt. Development of an understanding of these consolidation processes in crushed salt has been fundamental to the design and analysis of a credible seal system.

Because crushed salt is an important seal material, its constitutive model must satisfy the needs of performance assessment and regulatory compliance. To gain an understanding of the crushed-salt consolidation processes, laboratory testing and theoretical model development have been conducted over the last several years. The WIPP crushed-salt material model or constitutive model, which relates stress and strain, predicts deformations and stresses in the underground sealing system. The magnitude of the stresses and strains throughout the isolation system determines the location and extent of the disturbed rock zone and serviceability of the seal components. Laboratory testing has been used to develop the constitutive model from a phenomenological viewpoint and to evaluate the material constants associated with the model. The objective of this report is to provide the current version of the mechanical material model appropriate for describing crushed-salt deformation.

1.2 EARLIER WORK

Crushed salt has received international attention over the past 20 years primarily within a repository setting. Thus, an earlier study [Callahan et al., 1995] searched the literature for constitutive models developed for crushed salt. Ten models, based to varying degrees on phenomenology, micromechanics, or empiricism, were found. Three of these models were selected for detailed examination. The three models are those attributable to Sjaardema and Krieg [1987], Zeuch and Holcomb [Zeuch, 1990], and Spiers and coworkers [Spiers and Brzesowsky, 1993]. These constitutive models were developed to reproduce hydrostatic (isostatic) consolidation laboratory tests and include only the volumetric strain component. The Sjaardema and Krieg model is empirical and was retained for comparative purposes since it has been used in the past for calculation of crushed-salt problems at the WIPP. The Zeuch and Holcomb model was constructed for nominally dry crushed salt and is based on isostatic hot-pressing models combined with dislocation creep. The Spiers and coworkers model was formulated for wet crushed-salt aggregates and is based on grain boundary diffusional pressure solution processes. These three models were modified to include other effects thought to be important for WIPP salt. A flow potential and associated three-dimensional generalization were developed for the models so that they could operate over a wide range of stress triaxialities (ratio of mean stress to effective or deviatoric stress) and be applicable to arbitrary states of stress. A database of applicable crushed-salt laboratory tests was constructed comprising 40 hydrostatic consolidation tests and 10 shear consolidation tests. The experimental data were fit to determine values for the material parameters associated with each of the models. The hydrostatic and shear consolidation tests and their combination were fit separately so that three different parameter value sets were obtained. If a constitutive model truly represents the material and the data are unbiased, changes in parameter values among fits would be minimal. However, in this earlier study, the change in the parameter values was significant. These three models performed about equally well with the modified Spiers model exhibiting moderate superiority.

Following completion of the earlier study [Callahan et al., 1995], the constitutive model formulation was found to be inadequate at high fractional densities. In addition, because of the heavy bias in the database toward hydrostatic consolidation tests and because none of the shear consolidation tests reached high enough fractional densities to exhibit positive lateral strains, the constants associated with the flow potential made it impossible for the simulated crushed salt to move toward a volume-preserving flow (as is exhibited by intact salt) as the fractional density approached one. Most of the test data in the crushed-salt laboratory database exhibit a positive lateral-to-axial strain-rate ratio; whereas, the lateral-to-axial strain-rate ratio is negative for a triaxial test conducted on intact salt. However, as the crushed salt consolidates, the lateral deformation must change direction at some density level (i.e., cease to move inward and begin to

move outward as is observed for the intact salt tests). In addition to being a function of the density, this change in lateral strain direction is also, undoubtedly, a function of the state of stress. Having identified these shortcomings in the crushed-salt model, two additional shear consolidation tests were conducted to expand the database at higher fractional densities near 0.8 [RE/SPEC Inc., 1996]. The functional form of the flow potential for the models was modified, and the models were refit to the database. This study, discussed in RE/SPEC Inc. [1996] and Callahan et al. [1996], resulted in satisfactory model predictions over a wide range of fractional densities and stress triaxialities. However, the governing deformation mechanisms for crushed salt with varying degrees of added moisture were contained independently in two separate models.

Thus, the next study [Callahan et al., 1998; Hansen et al., 1998] incorporated the governing mechanisms — dislocation creep and pressure solution — into a single model. In addition, four new laboratory shear consolidation experiments were conducted with fractional densities near the initial fractional density (approximately 0.9) expected in the dynamically compacted crushed-salt seal [Sandia National Laboratories, 1996]. These tests expanded the database into fractional density ranges previously untested and provide information on the crushed-salt flow behavior as its density increases. These tests were added to the experimental database, which was fit to obtain material parameter values for the crushed-salt, combined-mechanism constitutive model. Up to this point, laboratory tests had included only hydrostatic and shear consolidation tests.

Laboratory testing was conducted in parallel with the constitutive model refinement work reported here. The laboratory work is reported separately [Mellegard et al., 1999] and includes test results from six shear consolidation tests and three constant strain-rate tests. Results from four of the shear consolidation tests have previously been considered in the constitutive model evaluation. The constitutive model development work reported here includes: (1) determination of the material model parameter values from the database updated with the two additional shear consolidation tests, (2) verification of the constitutive model through prediction of the constant strain-rate tests, and (3) demonstration of the constitutive model predictions for typical shaft sealing problems and comparison with earlier results.

1.3 REPORT ORGANIZATION

This report focuses on the mechanical constitutive behavior of crushed salt. In particular, Chapter 2.0 summarizes the constitutive model, provides the three-dimensional generalization of the model, and reduces the general model form to response models for specific types of laboratory tests used in the model fitting process. Chapter 3.0 summarizes the crushed-salt experimental database, along with recently completed tests used to fit the constitutive model and determine its material constants. Chapter 4.0 describes the nonlinear least-squares fitting procedure used to fit the constitutive model to the experimental database and presents the resulting parameter values. Chapter 5.0 presents verification of the constitutive model through prediction of constant strain-rate tests. Chapter 6.0 presents the results of typical shaft sealing calculations and compares the results to earlier versions of the constitutive model. The final chapter (Chapter 7.0) includes a summary and conclusions, which is followed by a list of references and three appendices.

2.0 CRUSHED-SALT CONSTITUTIVE MODEL

Details of the crushed-salt constitutive model that combine the dislocation creep and pressure solution deformation mechanisms are presented in detail by Hansen et al. [1998]. Therefore, this chapter simply summarizes the constitutive model equations for use later in the report. The chapter includes the general form of the crushed-salt constitutive model, the three-dimensional generalization for the creep consolidation model, and the reduction of the constitutive model to specific laboratory test forms used to fit the laboratory data and evaluate the material model parameters. Tensile stresses and extensile strains are assumed to be positive throughout this report.

2.1 GENERAL FORM OF THE CRUSHED-SALT CONSTITUTIVE MODEL

The total strain rate for the crushed-salt constitutive model is assumed to consist of two components. The components include nonlinear elastic $\left(\dot{\epsilon}_{ij}^{e} \right)$ and creep consolidation $\left(\dot{\epsilon}_{ij}^{c} \right)$ contributions, and the total strain rate is written as:

$$\dot{\epsilon}_{ij} = \dot{\epsilon}_{ij}^{e} + \dot{\epsilon}_{ij}^{c} \tag{2-1}$$

When the strains become finite, the expressions for strain rate should be interpreted as the rate of deformation. Both the nonlinear elastic and creep consolidation portions of the model describe the material behavior in bulk (volumetric) and in shear (deviatoric). However, as shown later, when the fractional density approaches unity, the creep consolidation portion of the model only describes deviatoric material behavior and is, in fact, the creep deformation model used for intact salt. The nonlinear elastic portion of the model presented by Callahan et al. [1995] has not changed and will not be presented again. The creep consolidation portion of the model is included in Hansen et al. [1998] and is summarized for use in the model fitting process discussed in Chapter 4.0. However, note that in this summary, parameter values η_2 and κ_2 included in Hansen et al. [1998] have been dropped since both are equal to one.

2.2 CREEP CONSOLIDATION MODEL

The creep consolidation model is of primary concern, and thus, this section is divided into subsections that summarize important portions of the crushed-salt consolidation model. Typically, equations proposed to describe the behavior of a particular material are written in one-dimensional form or as scalar relationships. To be useful in numerical analyses and applicable to a variety of laboratory experiments with different load paths, constitutive models must be generalized to include three-dimensional states of stress. The first subsection presents the generalization of the creep consolidation model. The next subsection collapses or reduces the generalized form of the creep consolidation equation to specific laboratory test conditions, which yields simplified forms that can be used in fitting the model to the experimental database. The

third subsection presents the effective strain-rate model forms that represent the two mechanisms associated with the crushed-salt creep consolidation component of the constitutive model.

2.2.1 Creep Consolidation Model Generalization

The creep consolidation constitutive equation for crushed salt includes two operative deformation mechanisms — dislocation creep and grain boundary diffusional pressure solution — and may be written as [Hansen et al., 1998]:

$$\dot{\epsilon}_{ij}^{c} = \left[\dot{\epsilon}_{eq}^{d}\left(\sigma_{eq}^{f}\right) + \dot{\epsilon}_{eq}^{w}\left(\sigma_{eq}^{f}\right)\right] \frac{\partial \sigma_{eq}}{\partial \sigma_{ij}} \tag{2-2}$$

where $\dot{\epsilon}_{ij}^{c}$ is the inelastic strain rate tensor and σ_{eq}^{f} is an equivalent stress measure. The equivalent inelastic strain rate measures for dislocation creep $\left(\dot{\epsilon}_{eq}^{d}\right)$ and pressure solution $\left(\dot{\epsilon}_{eq}^{w}\right)$ are written as functions of the equivalent stress measure. For use in the flow potential, another equivalent stress measure, σ_{eq}, is used to provide a nonassociative type of formulation that provides flexibility in governing the magnitude of the volumetric behavior. The equivalent stress measures are homogeneous of degree one in terms of stress and are given by:

$$\sigma_{eq}^{f} = \left[\eta_0 \Omega_f^{\eta_1} \sigma_m^2 + \left(\frac{2 - D}{D} \right)^{\frac{2n_f}{n_f+1}} \left(\sigma_1 - \sigma_3\right)^2 \right]^{1/2}$$

$$\sigma_{eq} = \left[\kappa_0 \Omega^{\kappa_1} \sigma_m^2 + \left(\frac{2 - D}{D} \right)^{\frac{2n}{n+1}} \left(\sigma_1 - \sigma_3\right)^2 \right]^{1/2} \tag{2-3}$$

$$\Omega_f = \left[\frac{(1 - D)\, n_f}{\left[1 - (1 - D)^{1/n_f}\right]^{n_f}} \right]^{\frac{2}{n_f+1}} \tag{2-4}$$

where:

$$\Omega = \left[\frac{\left(1 - D_v\right) n}{\left[1 - \left(1 - D_v\right)^{1/n}\right]^{n}} \right]^{\frac{2}{n+1}} \tag{2-5}$$

$$D_v = \begin{cases} D_t & D \le D_t \\ D & D > D_t \end{cases} \tag{2-6}$$

D = current fractional density

σ_m = mean stress = $\frac{\sigma_{kk}}{3}$

σ_3 = minimum principal stress

σ_1 = maximum principal stress

η_o, η_1, κ_0, κ_1, n_f, n, and D_t = material parameters.

As crushed salt approaches full consolidation (i.e., $D \rightarrow 1$), Ω_f and Ω approach zero, and the dependence on mean stress diminishes, which is required for an incompressible material matrix. Thus, letting $D = 1$, Equation 2-3 becomes:

$$\sigma_{eq}^{f} = \sigma_1 - \sigma_3 \qquad (2\text{-}7)$$

$$\sigma_{eq} = \sigma_1 - \sigma_3$$

Twice the maximum shear stress or Tresca equivalent stress is used in the equivalent stress measures to describe the shear behavior as is common for intact salt and is given by:

$$\sigma_1 - \sigma_3 = 2\cos\psi J_2 \qquad (2\text{-}8)$$

with the second and third invariants (J_2 and J_3) of the deviator stress $\left(s_{ij}\right)$ defined by:

$$J_2 = \frac{1}{2}s_{ij}s_{ji} \qquad (2\text{-}9)$$

$$J_3 = \frac{1}{3}s_{ij}s_{jk}s_{ki}$$

where the Lode angle (ψ), which is a convenient alternative invariant to J_3, is given by:

$$\psi = \frac{1}{3}\sin^{-1}\left[\frac{-3\sqrt{3}J_3}{2J_2^{3/2}}\right], \left(-\frac{\pi}{6} \le \psi \le \frac{\pi}{6}\right) \qquad (2\text{-}10)$$

The partial derivative given in Equation 2-2 may be determined using the chain rule as:

$$\frac{\partial \sigma_{eq}}{\partial \sigma_{ij}} = \frac{\partial \sigma_{eq}}{\partial \sigma_m}\frac{\partial \sigma_m}{\partial \sigma_{ij}} + \frac{\partial \sigma_{eq}}{\partial J_2}\frac{\partial J_2}{\partial \sigma_{ij}} + \frac{\partial \sigma_{eq}}{\partial \psi}\frac{\partial \psi}{\partial J_3}\frac{\partial J_3}{\partial \sigma_{ij}} \tag{2-11}$$

The derivatives of the invariants in Equation 2-11 are the same regardless of the invariant stress and strain measures selected. These derivatives are:

$$\frac{\partial \sigma_m}{\partial \sigma_{ij}} = \frac{\delta_{ij}}{3}$$

$$\frac{\partial J_2}{\partial \sigma_{ij}} = s_{ij} \tag{2-12}$$

$$\frac{\partial \psi}{\partial J_3}\frac{\partial J_3}{\partial \sigma_{ij}} = -\frac{\sqrt{3}}{2J_2^{3/2}\cos 3\psi} t_{ij}$$

where:

$$\delta_{ij} = \text{Kronecker delta}$$

$$t_{ij} = s_{ip}s_{pj} - \frac{2}{3}J_2\delta_{ij}.$$

Equation 2-11, defining the flow potential, also requires the partial derivatives of the equivalent stress measure (Equation 2-3) with respect to stress. Performing the required differentiation yields:

$$\frac{\partial \sigma_{eq}}{\partial \sigma_m} = \frac{\kappa_0 \Omega^{\kappa_1} \sigma_m}{\sigma_{eq}}$$

$$\frac{\partial \sigma_{eq}}{\partial J_2} = \frac{2}{\sigma_{eq}}\left(\frac{2-D}{D}\right)^{\frac{2n}{n+1}} \frac{\cos\psi \cos 2\psi}{\cos 3\psi} \tag{2-13}$$

$$\frac{\partial \sigma_{eq}}{\partial \psi} = -\frac{4}{\sigma_{eq}}\left(\frac{2-D}{D}\right)^{\frac{2n}{n+1}} \cos\psi \sin\psi J_2$$

Substituting Equations 2-11, 2-12, and 2-13 into Equation 2-2 provides the tensorial strain-rate components for the creep consolidation portion of the crushed-salt model, which is given by:

$$\dot{\epsilon}_{ij}^{c} = \frac{\dot{\epsilon}_{eq}^{d} + \dot{\epsilon}_{eq}^{w}}{\sigma_{eq}} \left\{ \frac{\kappa_0 \Omega^{\kappa_1} \sigma_m}{3} \delta_{ij} + \left(\frac{2 - D}{D} \right)^{\frac{2n}{n+1}} 2\sqrt{J_2} \cos\psi \left(\left[\frac{\cos 2\psi}{\cos 3\psi} \right] \frac{s_{ij}}{\sqrt{J_2}} + \left[\frac{\sqrt{3} \sin\psi}{J_2 \cos 3\psi} \right] t_{ij} \right) \right\} \tag{2-14}$$

Equation 2-14 is seen to be undefined as the Lode angle approaches $\pm\pi/6$. In other words, the flow potential forms corners at $\psi = \pm\pi/6$, and the direction of straining is not unique. To eliminate this problem computationally, the flow potentials on either side of the corner are averaged, which produces an indeterminant form that is examined in the limit as $\psi \rightarrow \pm\pi/6$. Performing this limiting operation, Equation 2-14 becomes:

$$\dot{\epsilon}_{ij}^{c} = \frac{\dot{\epsilon}_{eq}^{d} + \dot{\epsilon}_{eq}^{w}}{\sigma_{eq}} \left\{ \frac{\kappa_0 \Omega^{\kappa_1} \sigma_m}{3} \delta_{ij} + \left(\frac{2 - D}{D} \right)^{\frac{2n}{n+1}} \sqrt{3 J_2} \left(\frac{s_{ij}}{\sqrt{3 J_2}} \mp \frac{t_{ij}}{2 J_2} \right) \right\} \tag{2-15}$$

The flow potential contains four material parameters (κ_0, κ_1, D_t, and n) that need to be determined from laboratory experiments. To complete the crushed-salt creep consolidation description, the kinetic equations describing dislocation creep and pressure solution in crushed salt need to be defined. In general, these kinetic equations could be a form of any specific model that captures the desired characteristics of the material deformation. Discussion of these specific forms is included in Sections 2.2.3 and 2.2.4 following presentation of Equation 2-15 reduced to specific laboratory test conditions.

2.2.2 Evaluation of Laboratory Test Equation Forms

To compare the crushed-salt constitutive equations to laboratory experiments, one needs to reduce the equations to the applicable test conditions. In particular, tests of interest are the hydrostatic compression, triaxial compression, and triaxial extension tests. To derive these forms, one simply needs to substitute the applicable test conditions into the constitutive equations and reduce them to their simplest forms. The hydrostatic compression test conditions can be easily obtained from the triaxial compression test conditions by letting the stress difference $\Delta\sigma = \sqrt{3J_2}$ equal zero. The directions $\{zz, yy, xx\}$ are taken as $\{33, 22, 11\}$, and the $\{zz\}$ direction is taken to be the axial direction. For convenience, the following variables are defined:

$$\alpha = \frac{\kappa_0 \Omega^{\kappa_1} \sigma_m}{3}$$

$$\beta = \left[\frac{2 - D}{D}\right]^{\frac{2n}{n+1}} \sqrt{3 J_2} \qquad (2\text{-}16)$$

Fitting of the constitutive model can be conveniently separated into two separate stages. The first step includes fitting the ratio of the lateral strain rate to the axial strain rate defined as $\mathbb{R}$ and written as:

$$\mathbb{R} = \frac{\dot{\epsilon}_l^c}{\dot{\epsilon}_a^c} \qquad (2\text{-}17)$$

Fitting the strain-rate ratio allows the parameter values associated with the flow potential (i.e., κ_0, κ_1, D_t, and n contained in α and β in Equation 2-16) to be determined independently of the other material parameter values. Obviously, the test data must contain experiments where the stress triaxiality conditions lie between zero and infinity for the fitting to be successful. This can be accomplished with the shear consolidation tests.

Reduction to Triaxial Compression Creep Test ($\psi = \pi/6$)

The triaxial compression creep test is prescribed by controlling a constant stress state defined by $\sigma_{zz} < \sigma_{xx} = \sigma_{yy}$. The axial ($a$), lateral ($l$), and volumetric ($v$) strain components and strain-rate ratio for the creep consolidation portion of the model may be determined from Equations 2-15, 2-16, 2-17, and the applied stress condition as:

$$\dot{\epsilon}_a^c = [\alpha - \beta] \frac{\dot{\epsilon}_{eq}^d + \dot{\epsilon}_{eq}^w}{\sigma_{eq}}$$

$$\dot{\epsilon}_l^c = \left[\alpha + \frac{\beta}{2}\right] \frac{\dot{\epsilon}_{eq}^d + \dot{\epsilon}_{eq}^w}{\sigma_{eq}}$$

$$\dot{\epsilon}_v^c = 3\alpha \frac{\dot{\epsilon}_{eq}^d + \dot{\epsilon}_{eq}^w}{\sigma_{eq}} \qquad (2\text{-}18)$$

$$\mathbb{R} = \frac{\alpha + \frac{\beta}{2}}{\alpha - \beta}$$

Reduction to Triaxial Extension Test ($\psi = -\pi/6$)

The triaxial extension creep test is prescribed by controlling a constant stress state defined by $\sigma_{zz} > \sigma_{xx} = \sigma_{yy}$. The axial ($a$), lateral ($l$), and volumetric ($v$) strain components and strain-rate ratio for the creep consolidation portion of the model may be determined from Equations 2-15, 2-16, 2-17, and the applied stress conditions as:

$$\dot{\epsilon}_a^c = \left[\alpha + \beta\right] \frac{\dot{\epsilon}_{eq}^d + \dot{\epsilon}_{eq}^w}{\sigma_{eq}}$$

$$\dot{\epsilon}_l^c = \left[\alpha - \frac{\beta}{2}\right] \frac{\dot{\epsilon}_{eq}^d + \dot{\epsilon}_{eq}^w}{\sigma_{eq}} \qquad (2\text{-}19)$$

$$\dot{\epsilon}_v^c = 3\,\alpha \frac{\dot{\epsilon}_{eq}^d + \dot{\epsilon}_{eq}^w}{\sigma_{eq}}$$

$$\mathbb{R} = \frac{\alpha - \frac{\beta}{2}}{\alpha + \beta}$$

2.2.3 Equivalent Inelastic Strain-Rate Form for Dislocation Creep

Dislocation creep of intact salt has been characterized by the Multimechanism Deformation (M-D) model [Munson, 1979; Munson and Dawson, 1979]. Thus, the equivalent inelastic strain rate measure for the dislocation creep portion of the crushed-salt model is taken to be the M-D material model. The only modification for application of the M-D model to crushed salt is replacing the intact salt effective stress measure with the effective stress measure given for crushed salt in Equation 2-3.

The model is written as:

$$\dot{\epsilon}_{eq}^d = F\,\dot{\epsilon}_s \qquad (2\text{-}20)$$

where $\dot{\epsilon}_{eq}^d$ is the kinetic equation and $\dot{\epsilon}_s$ is the steady-state strain rate. The transient function F consists of three branches — a work-hardening branch, an equilibrium branch, and a recovery branch and is written in that order as:

$$F = \begin{cases} \exp\left[\Delta\left(1 - \dfrac{\zeta}{\epsilon_t^f}\right)^2\right] & \zeta < \epsilon_t^f \\ 1 & \zeta = \epsilon_t^f \\ \exp\left[-\delta\left(1 - \dfrac{\zeta}{\epsilon_t^f}\right)^2\right] & \zeta > \epsilon_t^f \end{cases} \tag{2-21}$$

Δ and δ are the work-hardening and recovery parameters, respectively, and ϵ_t^f is the transient strain-rate limit. The internal variable ζ is governed by the evolution equation:

$$\dot{\zeta} = (F - 1)\,\dot{\epsilon}_s \tag{2-22}$$

and the transient strain limit is given by:

$$\epsilon_t^f = K_0 e^{cT}\left(\frac{\sigma_{eq}^f}{\mu}\right)^m \tag{2-23}$$

where:

T = absolute temperature

μ = shear modulus

K_0, c, and m = material parameters.

The work-hardening parameter is defined as a function of stress:

$$\Delta = \alpha + \beta \log\left(\frac{\sigma_{eq}^f}{\mu}\right) \tag{2-24}$$

where α and β are material parameters. Because of insufficient data, the recovery parameter (δ) is taken to be a constant. However, functional forms similar to Equation 2-24 are sometimes used for recovery; viz:

$$\delta = \alpha_r + \beta_r \log\left(\frac{\sigma_{eq}^f}{\mu}\right) \tag{2-25}$$

where α_r and β_r are material parameters.

The steady-state strain rate is the sum of the three individual strain-rate mechanisms acting together:

$$\dot{\epsilon}_s = \sum_{i=1}^{3} \dot{\epsilon}_{s_i} \tag{2-26}$$

The three contributing mechanisms — dislocation climb, an undefined mechanism, and slip — are written respectively as:

$$\dot{\epsilon}_{s_1} = A_1 \left(\frac{\sigma_{eq}^f}{\mu} \right)^{n_1} \exp\left(-\frac{Q_1}{RT} \right) \tag{2-27}$$

$$\dot{\epsilon}_{s_2} = A_2 \left(\frac{\sigma_{eq}^f}{\mu} \right)^{n_2} \exp\left(-\frac{Q_2}{RT} \right) \tag{2-28}$$

$$\dot{\epsilon}_{s_3} = \left(B_1 e^{-Q_1/RT} + B_2 e^{-Q_2/RT} \right) \sinh\left[q \left(\frac{\sigma_{eq}^f - \sigma_0}{\mu} \right) \right] H\left(\sigma_{eq}^f - \sigma_0 \right) \tag{2-29}$$

where:

μ = shear modulus

q = activation volume

A_1, A_2, B_1, B_2, n_1, n_2, Q_1, Q_2, and σ_0 = experimental constants

R = universal gas constant

$H(.)$ = Heaviside step function.

2.2.4 Equivalent Inelastic Strain-Rate Form for Pressure solution

Spiers and Brzesowsky [1993] presented a grain boundary diffusional pressure solution model for wet crushed salt as:

$$\dot{e}_v^w = A V_m \frac{\exp\left(-\frac{Q_s}{RT}\right)}{T} \left(\frac{\sigma_m - P}{d^p}\right) \left(\frac{(1 + e_v)^{r_3}}{|e_v|^{r_4}}\right) \Gamma \tag{2-30}$$

where $\dot{e}_v^w$ is the volumetric consolidation strain rate, A, V_m, Q_s, p, r_3, and r_4 are material constants; T is absolute temperature; R is the universal gas constant; d is the grain size; and P is the pore pressure. The model consists of two functional forms — one for small strain and one for large strain, which are invoked depending on the prescribed value for Γ given as:

$$\Gamma = \begin{cases} 1 & \text{small strain } (e_v > -15\%) \\ \left[\dfrac{e_v + \phi_0}{\phi_0(e_v + 1)}\right]^{n_s} & \text{large strain } (e_v < -15\%) \end{cases} \tag{2-31}$$

where ϕ_0 is the initial porosity and n_s is a material parameter. Spiers and Brzesowsky [1993] developed the function Γ to account for increasing surface contact (increasing area and decreasing stress) as the strains become large. This geometrically interpreted variable serves to decrease the magnitude of the driving force.

Spiers and Brzesowsky's model is used to represent the equivalent inelastic strain-rate form for pressure solution with modifications. The functional form given in Equation 2-30 is modified by changing the stress-dependent term (using the equivalent stress measure defined in Equation 2-3) and adding the effect of moisture (w is the moisture fraction by weight). The moisture function (simply w raised to a power, a) eliminates any strain-rate contribution to the crushed-salt consolidation model when moisture content is zero. In addition, the pore pressure dependency (parameter P in Equation 2-30) has been dropped from the model because insufficient test data are available to include pore pressure as a state variable. With these modifications, the modified Spiers' model used to define the kinetic equation becomes:

$$\dot{e}_{eq}^w = \frac{r_1 w^a}{d^p} \frac{e^{-\frac{Q_s}{RT}}}{T} \left(\frac{(1 + e_v)^{r_3}}{|e_v|^{r_4}}\right) \Gamma \sigma_{eq}^f \tag{2-32}$$

Notice that material constants A and V_m appearing in Equation 2-30 have been combined into one parameter, r_1, in Equation 2-32 defined as:

$$r_1 = AV_m = \text{material constant} \left[\frac{\text{m}^p \cdot K}{\text{MPa} \cdot \text{s}}\right] \tag{2-33}$$

Moisture content and grain size are not implemented specifically in numerical models since their distributions are generally not known and they are assumed to be constants. However, the moisture and grain size effects are incorporated through the leading coefficient, which may be corrected for changes in grain size and moisture. Thus, the corrected leading coefficient is

$$r_1^* = \frac{r_1 w^a}{d^p} \tag{2-34}$$

To express the pressure solution model in terms of true strain (ϵ), consider the following relationships:

$$\begin{aligned} \epsilon_v &= \ln\left(\frac{\rho_0}{\rho}\right) \\ \epsilon_v &= \ln\left(1 + e_v\right) \\ \dot{\epsilon}_v &= \frac{\rho}{\rho_0}\dot{e}_v = e^{-\epsilon_v}\dot{e}_v \end{aligned} \tag{2-35}$$

Using Equation 2-35, Equation 2-32 may be written as:

$$\dot{\epsilon}_{eq}^w = r_1^* e^{-\epsilon_v}\left(\frac{e^{r_3\epsilon_v}}{\left|e^{\epsilon_v} - 1\right|^{r_4}}\right)\frac{e^{-\frac{Q_s}{RT}}}{T}\,\Gamma\,\sigma_{eq}^f \tag{2-36}$$

which is the form incorporated into SPECTROM-32, a thermomechanical finite element stress analysis program [Callahan et al., 1989], with the geometric factor written as:

$$\Gamma = \begin{cases} 1 & \text{small strain } \left(e^{\epsilon_v} - 1 > -15\%\right) \\ \left[\dfrac{e^{\epsilon_v} + \phi_0 - 1}{\phi_0 e^{\epsilon_v}}\right]^{n_s} & \text{large strain } \left(e^{\epsilon_v} - 1 < -15\%\right) \end{cases} \tag{2-37}$$

A problem is evident in Spiers' model at time zero. Equation 2-30 or 2-36 can be indeterminate since when $\sigma_{eq}^{f} = 0$, the initial volumetric strain is zero. To eliminate this problem during computations, some initial value must be assumed for the volumetric strain. Typically, this initial strain value will be computed based on an original fractional density of 0.64, which is the approximate fractional density for random-dense packing of single size spheres (Fischmeister and Arzt [1983] and Helle et al. [1985]), and the fractional density at the beginning of creep consolidation. The pressure solution model has seven material constants — a, p, Q_s, r_1, r_3, r_4, and n_s, excluding those that appear in the effective stress measure.

2.3 SUMMARY OF THE CRUSHED-SALT CONSOLIDATION MODEL

The equation describing the combined-mechanism, crushed-salt constitutive model, which includes dislocation creep and pressure solution, is summarized in this section. The final equation for the total creep consolidation strain rate is obtained by substituting Equations 2-20 and 2-36 into Equation 2-14:

$$\dot{\epsilon}_{ij}^{c} = \frac{1}{\sigma_{eq}} \left\{ \frac{r_1 w^{a}}{d^{p}} e^{-\epsilon_v} \left(\frac{e^{r_3 \epsilon_v}}{\left| e^{\epsilon_v} - 1 \right|^{r_4}} \right) \frac{e^{-\frac{Q_s}{RT}}}{T} \Gamma \sigma_{eq}^{f} + F \dot{\epsilon}_{s} \right\} \times$$

$$\left\{ \frac{\kappa_0 \Omega^{\kappa_1} \sigma_m}{3} \delta_{ij} + \left(\frac{2-D}{D} \right)^{\frac{2n}{n+1}} \left(2 \cos\psi \sqrt{J_2} \right) \left(\left[\frac{\cos 2\psi}{\cos 3\psi} \right] \frac{s_{ij}}{\sqrt{J_2}} + \left[\frac{\sqrt{3} \sin\psi}{J_2 \cos 3\psi} \right] t_{ij} \right) \right\} \tag{2-38}$$

As the material approaches full consolidation, the fractional density approaches 1, and the M-D model creep component becomes the same as that for intact salt. Simultaneously, the pressure solution portion of the model diminishes as the material approaches full consolidation. This decrease is implemented through the geometric Γ function, which becomes zero at full consolidation. Thus, at complete consolidation (i.e., $D = 1$), Equation 2-38 may be written as:

$$\dot{\epsilon}_{ij}^{c} = F \dot{\epsilon}_{s} \left(\left[\frac{\cos 2\psi}{\cos 3\psi} \right] \frac{s_{ij}}{\sqrt{J_2}} + \left[\frac{\sqrt{3} \sin\psi}{J_2 \cos 3\psi} \right] t_{ij} \right) \tag{2-39}$$

which is identical to the M-D model for intact salt.

3.0 EXPERIMENTAL DATABASE

A database of crushed-salt consolidation laboratory test results was assembled, analyzed, and reported in previous work [Callahan et al., 1995; 1998a]. This previous work initiated the process of formulating the functional form of a constitutive model for crushed salt and assembled existing test data into a database to obtain quantitative estimates for the material parameters appearing in the model. The assembled database consists of a collection of tests conducted for a variety of reasons. Thus, the database contains biases and shortcomings when viewed strictly from the standpoint of developing constitutive models. The crushed-salt constitutive model has deviatoric and mean stress components that drive the strain response, and the database has shear and hydrostatic consolidation tests used for evaluating the parameters within those respective stress components. Since this initial work was completed, additional tests have been conducted to fill gaps in the database. Two additional shear consolidation tests [RE/SPEC Inc., 1996; Callahan et al., 1998a] were conducted and added to the database following compilation of the initial database. These two tests represent the first tests with high initial fractional densities (near 0.8) that emulate intact salt behavior accompanied by volumetric consolidation. Subsequently, four additional tests were conducted to add test data to the shear consolidation portion of the extant database because that portion of the database was relatively sparse, particularly in the higher initial fractional density range expected at WIPP. These four additional shear consolidation tests on dynamically compacted crushed salt are summarized by Hansen et al. [1998] and Mellegard et al. [1999].

Two new shear consolidation tests were conducted in parallel with the current study to add test data to the shear consolidation portion of the database and verify earlier test results. In addition, three constant strain-rate tests were performed to provide experimental results and load paths outside of the fitted database for verification of the constitutive model. The remainder of this chapter is divided into two sections; the first section summarizes the status of the database used for evaluation of material parameter values and the second section presents details on the two new shear consolidation tests. The three constant strain-rate tests that were performed in parallel with the current effort are discussed in chapter 5.0.

3.1 SUMMARY OF EXISTING TEST DATA

Creation of the database was initiated with an extensive library search and compilation of potentially useful test results [Pfeifle, 1995]. The test data were compiled from the original studies conducted by Holcomb and Hannum [1982], Pfeifle and Senseny [1985], Holcomb and Shields [1987], Zeuch et al. [1991], and Brodsky [1994]. That compilation was reviewed to document those tests deemed inappropriate for parameter estimation and the surviving tests formed the database for parameter estimation work [Callahan et al., 1995]. Subsequently, six shear consolidation tests were added to the database for constitutive model evaluation and

parameter estimation in two different studies: Callahan et al. [1998a] — two tests and Hansen et al. [1998] — four tests. The database is constructed from two types of tests: hydrostatic consolidation and shear consolidation. The two parts of the database are shown separately in Tables 3-1 and 3-2, which summarize the tests for the hydrostatic and shear consolidation groupings, respectively.

Table 3-1 lists 40 tests contained in the hydrostatic consolidation portion of the database. All of the testing was performed in a drained condition; i.e., the pore pressure was zero. The database discussed by Callahan et al. [1995] contained 45 tests. Five of the hydrostatic consolidation tests were eliminated from the database, as recommended by Callahan et al. [1995]. These tests were performed under saturated conditions and were not very well drained, which resulted in the generation of pore pressures with reduced deformation. The maximum and minimum principal stresses are listed under the columns titled σ_1 and σ_3. The principal stresses are equal for the hydrostatic case, but the formatting of the table has been maintained for both types of tests. The initial dry density of the specimens, the density at the beginning of the consolidation stage, and the final density at the end of the test are given under the respective column headings titled ρ_o, ρ_i, and ρ_f.

Table 3-2 lists the shear consolidation tests in the database and is formatted the same as Table 3-1. The table contains the 16 tests that were used in previous work and two additional tests that were conducted in parallel with the current work. As with the hydrostatic consolidation tests, all of the shear consolidation tests were performed in a drained condition.

The tests listed in Tables 3-1 and 3-2 represent 58 tests (40 hydrostatic consolidation tests and 18 shear consolidation tests) and comprise the entire database used for parameter estimation discussed in Chapter 4.0. The original data files often contained thousands of data points, which presented an impractical size for regression analyses. Each data file was reduced in size to create representative data sets containing only 100 data points with the first and last data points always being retained and the remaining data points uniformly sampled. This sampling technique is the same as was used in previous work. Tables 3-1 and 3-2 present the nominal or target test conditions for temperature and stress. The actual test conditions achieved are shown in Tables 3-3 and 3-4. The values for temperature and stress in these tables were determined by computing the time-weighted averages from the 100-point data files. As can be seen, the actual test conditions are moderately different than the targeted test conditions.

3.2 DESCRIPTION OF RECENT LABORATORY TESTS

Since the status of the crushed-salt constitutive model was reported by Callahan et al. [1998b] and Hansen et al. [1998], five additional laboratory tests have been completed and are included in the present work. Two of these tests are shear consolidation tests; three of the tests are constant strain-rate tests. These tests have been reported separately by Mellegard et al. [1999]. The shear consolidation tests are included in the crushed-salt database used to determine parameter values for the constitutive model and will be summarized here. The constant strain-rate tests are used to verify the constitutive model and are discussed in chapter 5.0.

The two shear consolidation creep tests were performed on dynamically compacted crushed-salt specimens that were fabricated with a laboratory-scale device following a procedure similar to that used for dynamic compaction of large-scale samples [Hansen and Ahrens, 1998]. This device simulated of the compaction technique envisioned for the shaft sealing design. The laboratory-scale device used two Proctor split compaction molds (American Society for Testing and Materials [1991a, 1991b]) to receive the disaggregated salt. After compaction, the molds were removed and the ends of the cylindrical samples were machined to produce testable specimens with nominal dimensions of 100 millimeters in diameter and 200 millimeters in length. The starting material was wetted with a brine so that the specimen moisture content was nominally 1.6 % by weight. The dry density of the specimens was about 1,950 kg/m^3, which is a fractional density of approximately 0.9 (assuming intact salt density of 2,160 kg/m^3). The energy input to create this density was approximately 2.6 times the modified Proctor energy (American Society for Testing and Materials [1991a, 1991b]). The specimens fabricated with the laboratory-scale device were identified with the unique labels, RS/DCCS/*n*, where *n* took on values of 10 and 15 to designate individual specimens. As shown in Table 3-2, four other shear consolidation tests on dynamically compacted crushed salt were performed previously.

Table 3-4. Time-Weighted Average Test Conditions for the Shear Consolidation Tests

RS/DCCS/4	1401 through 1500	297	–6.99	–3.00
RS/DCCS/5	1501 through 1600	298	–7.99	–4.00
RS/DCCS/10	1601 through 1700	297	–9.01	–5.00
RS/DCCS/15	1701 through 1800	298	–5.00	–1.01

The two shear consolidation tests were effectively standard triaxial compression creep tests ($\psi = \pi/6$) and typical test procedures have been described previously [Callahan et al., 1995; Brodsky, 1994]. The specimens were initially loaded hydrostatically to the level of specified confining pressure (lateral stress) and allowed to stabilize. The specified confining pressure levels for the two tests were –5 and –1 MPa. Data were collected during the hydrostatic loading phase. Following stabilization, the axial compressive stress for each test was increased by 4 MPa while holding the confining pressure constant so that each specimen was subjected to a stress difference of $\Delta\sigma = 4$ MPa; only the confining pressure was different for the two tests. Data were also acquired when the axial stress difference was applied. After the axial stress difference was imposed, it was held constant while data were acquired during the shear consolidation creep phase. The test matrix for the shear consolidation creep tests is shown in Table 3-5 where the first column contains the specimen identification and the following three columns give the axial stress, lateral stress, and temperature, respectively, based on the time-weighted average of the actual laboratory data. Both tests were performed in a drained condition; i.e., the pore pressure was zero.

Table 3-5. Shear Consolidation Creep Test Matrix

Specimen Identification	Test Conditions		
	Axial Stress (MPa)	Lateral Stress (MPa)	Temperature (°C)
RS/DCCS/10	–9.01	–5.00	24
RS/DCCS/15	–5.00	–1.01	25

Earlier analyses (based on the constitutive model) predicted that a stress state existed where the lateral strain rate would initially be negative (compaction) and then reverse direction and become positive as the specimen density increased. The scheme for finding this stress state was to change the mean stress by testing at different confining pressures while holding the axial stress difference constant, as reported by Hansen et al. [1998]. The four tests completed previously (see Table 3-2) were run at confining pressures of –1, –2, –3, and –4 MPa all with a stress difference of 4 MPa. Thus, Test RS/DCCS/10 is simply the next test in that progression; whereas, Test RS/DCCS/15 is a repeat of the first test. The creep strain results from the two tests are compared in Figure 3-1, which plots axial and lateral creep strains as a function of time.

A very significant phenomenon is observed in Test RS/DCCS/10: *the lateral strain rate was initially negative (specimen diameter decreasing) and after some densification of the specimen, the lateral strain rate decreased and ultimately changed sign and became positive (specimen diameter increasing)*. This observation is important to the work presented in Chapter 4.0, where the parameters of the crushed-salt constitutive model are determined. As stated earlier, this behavior is known to exist because as crushed salt consolidates and approaches full consolidation, its behavior has to become similar to that of intact salt. However, to be able to accurately capture this behavior in a constitutive model, the phenomenon must be included in the database so that the fitted parameter values capture the full range of material behavior.

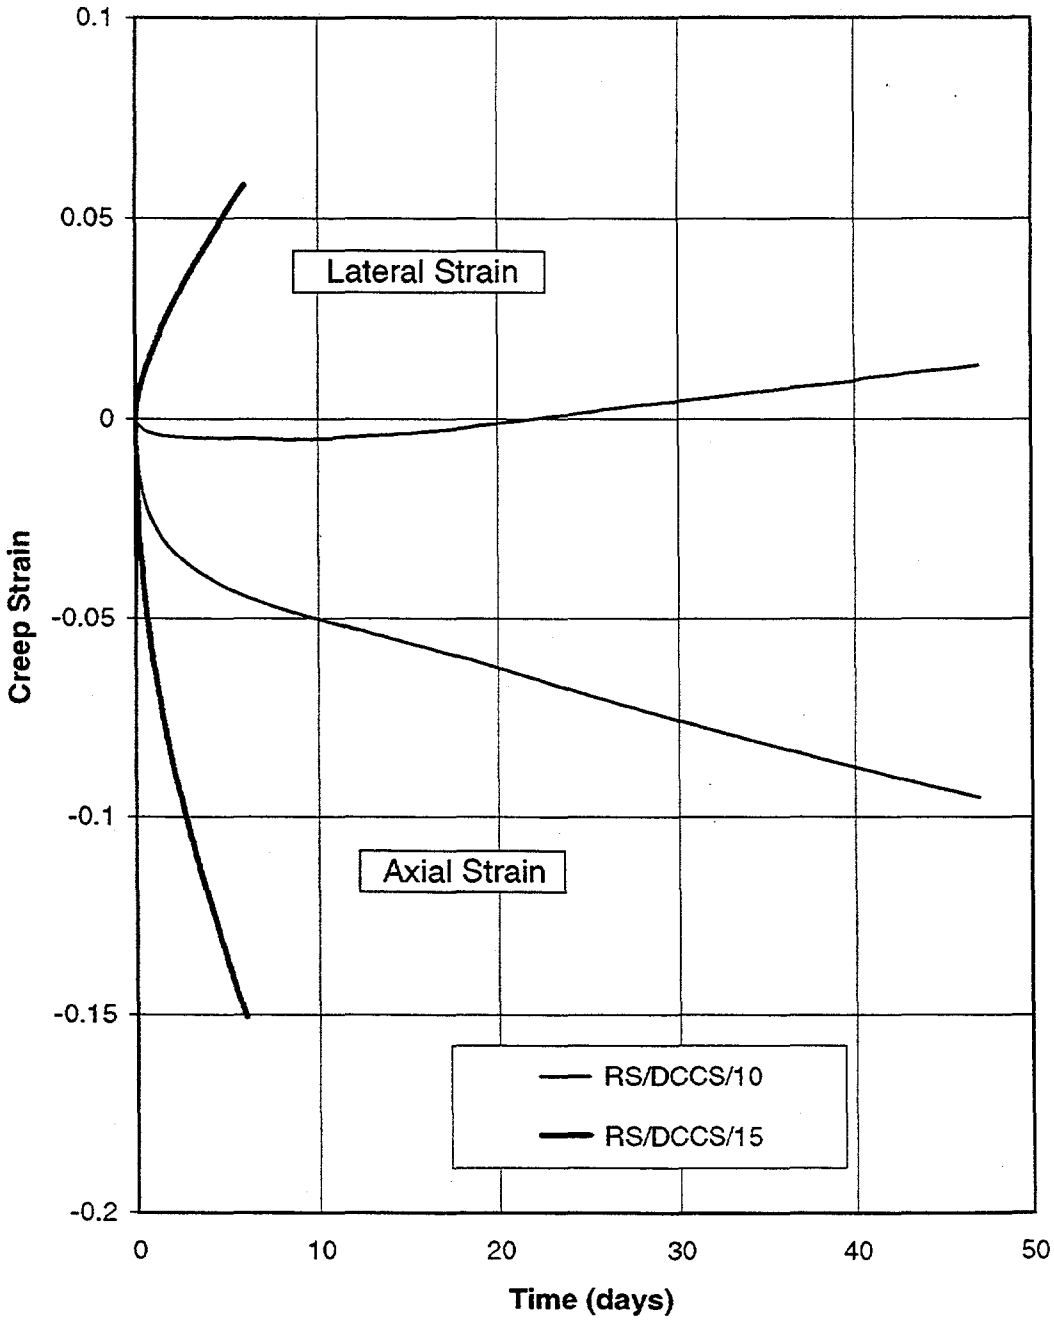

Figure 3-1. Axial and lateral strain as a function of time for two, shear consolidation creep tests on dynamically compacted crushed salt.

4.0 MODEL FITTING

4.1 INTRODUCTION

The crushed-salt constitutive model given in Equation 2-38 contains 31 material parameters. Seventeen of these material parameters are contained in the dislocation creep (M-D) portion of the model. The M-D model parameters were fixed at the values provided by Munson et al. [1989] for clean salt. The pressure solution portion of the model contains seven material parameters, and the remaining seven material parameters comprise four flow potential material parameters and three equivalent stress measure parameters. These 14 remaining parameters were determined by fitting the equations that define the crushed-salt constitutive model to the laboratory data such that the weighted squared difference between the measured and calculated response was minimized. First, the flow potential parameters (κ_0, κ_1, n, and D_t) were determined by fitting Equation 2-18, which defines the lateral-to-axial strain-rate ratio, to the data measured in the 18 shear consolidation tests. Second, these flow rate parameters were fixed and the ten creep consolidation parameters (η_0, η_1 , n_f, a, p, n_s, r_1, r_3, r_4, and Q_s/R) were determined by fitting the rate equations that define the axial and lateral strains to the data measured in the 18 shear consolidation and 40 hydrostatic consolidation tests. These nonlinear regressions were performed using the personal-computer platform BioMedical Data Processing (BMDP, Version 7.01) statistical software package.

4.2 MODELING PROCEDURE

The *object function* is the mathematical function that is to be minimized in the least-squares sense. For example, when performing a least-squares fit of some data to a straight line, the object function is the squared difference between the measured response (the data) and the predicted response from the equation for the straight line. The equation for the straight line when performing linear regression is called the *response model.*

The object function is evaluated at discrete points. These points are the points where data have been taken or are available. Some of the measurements may be more important than others and should hold more importance or *weight* than other data points. Mathematically, the relative importance of the level of fit to each data point is accommodated through a *weighting function.*

Application of least-squares minimization results in an estimation of the parameters of the response model. In the example cited above, application of least-squares will result in the estimation of the two parameters necessary to specify a straight line under the implicit assump-

tion that the measurements will be distributed about the response model for fixed values of the (hopefully) independent parameters. For complex nonlinear models, the independence of the parameters is not always obvious before fitting. The parameters obtained from a least-squares fit to a nonlinear model may not be appropriate if the parameters are highly correlated.

The response model will almost never reproduce all of the measurements exactly. The difference between the measured data points and the predicted model response is termed the *residual*. When a weighting function is used in the model fitting, the weighted residual is also of interest. The weighted residual is the usual residual multiplied by the weighting function value for the specific observation or data point.

The object function for the crushed-salt constitutive model was developed under the following assumptions and reflects the relative importance associated to individual data points:

- Within a given test, there are an equal number of measurement points (100). Each data point was assumed to have equal weight.
- Within each test, the data are not uniformly distributed with respect to time; the data are more dense early in time when the strain rates are highest. Thus, the weight function that was used in the model fitting reflects the time-step size relative to each data point in each test, such that higher weights are assigned to data points at the end of the test than are assigned to early-time data points.
- Tests of longer duration were assumed to be more important than tests of shorter time duration.
- Residuals were normalized. They are represented as percent deviations from the measured data. Thus, a 10-% deviation from a very small strain results in the same error in the object function as a 10-% deviation from a very large strain.

4.2.1 Response Functions

In the shear consolidation tests, there are two independent measurements (superscript m is used to indicate measurements); namely, the volumetric strain $\left(\epsilon_v^m\right)$ and the axial strain $\left(\epsilon_a^m\right)$. The lateral strain $\left(\epsilon_l^m\right)$ is calculated as:

$$\epsilon_l^m = \frac{\epsilon_v^m - \epsilon_a^m}{2} \tag{4-1}$$

The axial strain rate $\left(\dot{\epsilon}_a^m\right)$ was calculated from the measurement of axial strain and elapsed time as follows. At every data point in the original test data file (some contained thousands of data points), the axial strain rate was calculated as the linear least-square fit to a small interval of data (window) centered on the point in time. The window was then shifted by one data point to

the next point in time and the linear fit was repeated. This process was repeated until a point was reached where the width of the window reached the end of the data file for each test. A 50-point window was used in this process. The lateral strain rate $\left(\dot{\epsilon}_l^m\right)$ was calculated in a similar fashion. The measured lateral-to-axial strain-rate ratio $(\mathbb{R}^m)$ is defined as (cf. Equations 2-17 and 2-18):

$$\mathbb{R}^m = \frac{\dot{\epsilon}_l^m}{\dot{\epsilon}_a^m} \tag{4-2}$$

Following the development in Chapter 2.0, the response function used to determine the flow potential parameters is:

$$\mathbb{R}^p = \frac{\alpha + \frac{\beta}{2}}{\alpha - \beta} \tag{4-3}$$

where:

$\mathbb{R}^p$ = predicted lateral-to-axial strain-rate ratio

$$\alpha = \frac{\kappa_0 \, \Omega^{\kappa_1} \, \sigma_m}{3}$$

$$\beta = \left(\frac{2 - D}{D}\right)^{\frac{2n}{n+1}} \left(\sigma_1 - \sigma_3\right)$$

$$\Omega = \left\{\frac{\left(1 - D_v\right)n}{\left[1 - \left(1 - D_v\right)^{1/n}\right]^n}\right\}^{\frac{2}{n+1}}$$

$$D_v = \begin{cases} D_t & D \le D_t \\ D & D > D_t \end{cases}$$

D = current fractional density

σ_m = mean stress = $(\sigma_3 + 2\sigma_1)/3$

σ_3 = minimum principal stress

σ_1 = maximum principal stress

and

κ_0, κ_1, n, and D_t = flow potential parameters.

The response function (λ) used to determine the creep consolidation parameters is:

$$\lambda = 1 - \left\{\left[(1 - R_1)^2 + (1 - R_2)^2\right] wt\right\}^{1/2} \tag{4-4}$$

where:

$R_1 = \epsilon_a^p / \epsilon_a^m$

$R_2 = \epsilon_l^p / \epsilon_l^m$

$wt = \Delta t / \bar{t}$ = weighting function

Δt = time-step size

$\bar{t}$ = normalizing time = 10^6(s)

ϵ_l^p = predicted lateral strain = $\int_o^t \dot{\epsilon}_l^p \, dt$

ϵ_a^p = predicted axial strain = $\int_o^t \dot{\epsilon}_a^p \, dt$

$\dot{\epsilon}_l^p$ = predicted lateral strain rate = $(\alpha + \beta/2) \dfrac{\dot{\epsilon}_{eq}}{\sigma_{eq}}$

$\dot{\epsilon}_a^p$ = predicted axial strain rate = $(\alpha - \beta) \dfrac{\dot{\epsilon}_{eq}}{\sigma_{eq}}$

$\dot{\epsilon}_{eq}$ = equivalent inelastic strain rate = $\dot{\epsilon}_{eq}^d + \dot{\epsilon}_{eq}^w$

σ_{eq} = equivalent stress measure = $\left[\kappa_o \, \Omega^{\kappa_1} \, \sigma_m^2 + \left(\dfrac{2 - D}{D}\right)^{\frac{2n}{n+1}} (\sigma_1 - \sigma_3)^2\right]^{1/2}$

$\dot{\epsilon}_{eq}^d$ = Munson-Dawson dislocation creep strain-rate model given in Equations 2-20 to 2-29

$\dot{\epsilon}_{eq}^w$ = Spiers pressure-solution inelastic strain-rate model given in Equations 2-36 and 2-37

and:

η_0, η_1, n_f, a, p, n_s,
r_1, r_3, r_4, and Q_s/R = creep consolidation parameters.

The Munson-Dawson dislocation creep model has 17 parameters, which are given in Table 4-1 for clean WIPP salt.

Table 4-1. M-D Model Parameter Values for Clean Salt

Parameter	Units	Clean Salt
A_1	yr^{-1}	$2.645 \cdot 10^{30}$
	s^{-1}	$8.386 \cdot 10^{22}$
A_2	yr^{-1}	$3.050 \cdot 10^{20}$
	s^{-1}	$9.672 \cdot 10^{12}$
Q_1/R	K	12,581
Q_1	cal/mol	25,000
Q_2/R	K	5,033

K_o	—	$6.275 \cdot 10^{5}$
c	K^{-1}	$9.198 \cdot 10^{-3}$
α	—	–17.37
β	—	–7.738
δ	—	0.58

4.2.2 Object Function

The object function is the sum-of-squared errors (SS_E). In determining the flow rate parameters, the sum-of-squared error is defined as:

$$SS_E = \sum_{i=1}^{N} \left(\mathbb{R}_i^p - \mathbb{R}_i^m \right)^2 \tag{4-5}$$

where:

R_i^p = predicted lateral-to-axial strain rate ratio for the ith data point (Equation 4-3)

R_i^m = measured lateral-to-axial strain rate ratio for the ith data point (Equation 4-2)

N = number of data points in test database.

To determine the creep consolidation parameters, the sum-of-squared error is defined as:

$$SS_E = \sum_{i=1}^{N} \left(1 - \lambda_i \right)^2 \tag{4-6}$$

where:

λ_i = response function defined in Equation 4-4 for the ith data point.

4.3 STATISTICAL MEASURES

One key aspect of the model-fitting effort is deciding if the model fit to one database is better than the fit to the other database. In this section, the statistical measures for evaluating and comparing fits to the crushed-salt constitutive model are discussed.

4.3.1 Weighted Residual

In all types of regression, the summation of weighted, squared residuals is the function that is minimized, where the residual is defined as the difference between the observed and predicted functional values. The sum-of-squared error term defined in Equation 4-6 was used in evaluating the model fits to two databases: (1) the shear consolidation tests only and (2) the combined shear and hydrostatic consolidation tests.

The specific weighting function associated with the sum-of-squared error is equal to the reciprocal of the measured axial strain squared $\left(\epsilon_a^m\right)^2$, the reciprocal of the measured lateral strain squared $\left(\epsilon_l^m\right)^2$, the time increment (Δt), and the reciprocal of a normalizing time $(10^6\ s)$. Thus, if the response model (Equation 4-4) predicts zero axial strain and zero lateral strain over the duration of all tests in the database, the term SS_E in Equation 4-6 will have a value of twice the number of million seconds in the database. This is termed the maximum value of the sum-of-squared error $\left(SS_E^{max}\right)$. The 40 hydrostatic consolidation tests constitute a total of $76.02(10^6)\ s$. The 18 shear consolidation tests total $73.93(10^6)\ s$. Therefore, $SS_E^{max} = 147.86$ in the fit to the shear tests, and $SS_E^{max} = 299.90$ in the fit to the combined test database.

In a similar fashion, if the response model is a perfect predictor for all of the tests in the database, the sum-of-squared error will be exactly zero. This is the minimum value of the sum-of-squared error.

For each model fit, the sum-of-squared error was normalized as follows:

$$0 \le \overline{SS_E} \le 1 \tag{4-7}$$

where:

$$\overline{SS_E} = SS_E / SS_E^{max}$$

The normalized sum-of-squared error is used to compare the model fits to the two databases.

4.3.2 Parameter Multicollinearity

When fitting a mathematical relation to a set of laboratory-measured data, it is desirable to have enough information in the measured database to ensure that each of the parameters can be uniquely determined. Two possibilities can occur that will not allow for a unique determination of each parameter in a mathematical relation. First, the mathematical relation may inherently include parameters that are dependent upon one another. For example, in the relation:

$$F = A + B \tag{4-8}$$

the parameters A and B cannot be determined uniquely.

Second, there may not be sufficient data in the database to uniquely determine the magnitude of certain model parameters. For example, there is minimal variation in grain size (d), moisture content (w), and temperature (T) in the shear consolidation tests ($\Delta\sigma \neq 0$). Thus, in fitting the crushed-salt constitutive model to these tests, the parameters p, a, and Q_s/R contained in the product of the functional forms containing them; i.e.,

$$\xi(d,w,T) = \frac{w^{a}}{d^{p}T} \exp\left(-Q_s/RT\right) \tag{4-9}$$

cannot be uniquely determined.

When either of the two aforementioned conditions exist, a condition of multicollinearity is said to exist [Montgomery and Peck, 1982]. An examination of the parameter covariance matrix illustrates the degree to which the material parameters are correlated to each other. The higher the parameter covariance, the higher the parameter collinearity. When a multicollinearity situation exists, one must (1) expand the database of measurements or (2) modify the functional form of the model.

The elements of the correlation matrix (C_{ij}) can be expressed as [Montgomery and Peck, 1982]:

$$C_{ij} = \frac{q_{ij}}{\sqrt{q_{ii}\, q_{jj}}} \tag{4-10}$$

where:

$q_{ij} = \left[z_{ip}\ z_{pj}\right]^{-1}$

$z_{ij} = \dfrac{\partial\ \epsilon^{m}\left(x_j, \overline{p}\right)}{\partial p_i}$

$\overline{p}$ = set of parameters taken at their mean values

p_i = i^{th} parameter

x_j = j^{th} model variable

ϵ^{m} = measured response.

If the parameters are uncorrelated, then $C_{ij} = 0$. Conversely, the correlation coefficient is one if the parameters are totally correlated. The parameters are highly correlated if $|C_{ij}| \geq 0.90$ and a state of parameter multicollinearity may exist.

A scalar quantity, termed the parameter correlation measure (pcm), was used in this study as a global measure of the parameter correlations associated with each model's fit to each database.

This measure is defined as:

$$\text{pcm} = \frac{\frac{1}{2}\left(\sum_{i=1}^{p}\sum_{j=1}^{p} C_{ij}^2 - p\right)}{\sum_{i=1}^{p-1} i} = \frac{2\sum_{i=2}^{p}\sum_{j=1}^{i-1} C_{ij}^2}{p^2 - p} \tag{4-11}$$

where p is the number of parameters in the model and $0 \leq \text{pcm} \leq 1$. The numerator in Equation 4-11 is the sum of the squares of the lower triangular components of the parameter correlation matrix (Equation 4-10), and the denominator simply normalizes the result by the number of components in the sum. Obviously, the lower the parameter correlations, the lower the magnitude of the parameter correlation measure. Finally, an average parameter correlation $(\bar{c})$ can be quantified as:

$$\bar{c} = \sqrt{pcm} \tag{4-12}$$

4.3.3 Parameter Variation Among Fits

The crushed-salt constitutive model was fit to two databases: (1) the shear consolidation tests only and (2) the combination of shear and hydrostatic consolidation tests. If a specific model is the true constitutive law for representing the consolidation of crushed salt, the material parameters in each of the different fits should be the same or nearly the same. To evaluate the parameter variation obtained in the fits, the ratio of the parameter values obtained in the two fits (combined database parameter values divided by shear database parameter values) are examined. If the parameter values change less than the one order of magnitude, the resulting ratio should be between 0.1 and 10.

4.3.4 Predictive Capability

The aptness of the crushed-salt constitutive model (predictive capability) can be demonstrated using the parameter values determined by fitting to the individual test databases. The material parameters determined in the fit to the shear consolidation tests were used to predict each of the hydrostatic consolidation tests. A quantitative measure of the predictive capability is simply the sum-of-squared error (Equations 4-5 and 4-6). This measure was calculated using the

BMDP Program AR (Section 4.4) by fixing the parameter values at those determined in the fit to the shear consolidation tests and fitting (predicting) the hydrostatic consolidation tests.

4.4 BMDP STATISTICAL SOFTWARE

This section describes the BioMedical Data Processing (BMDP) nonlinear regression Programs 3R and AR used in the model fitting. BMDP is a statistical software package developed at the University of California at Berkeley supported by grants from the Biotechnology Resources Branch of the National Institutes of Health and the National Science Foundation.

BMDP Program AR is a nonlinear regression program that estimates the parameters of a nonlinear function by least squares using a pseudo Gauss-Newton algorithm. The response model can be specified as a system of coupled rate equations. The response model derivatives are evaluated numerically based on the initial parameter estimates and are not updated during the regression. In addition to calculating the weighted sum-of-squared error (SS_E), the program calculates the coefficient of multiple determination (R_p^2), the residual mean-squared error (MS_E), and the coefficients of the parameter correlation matrix (C_{ij}). The various program features and supporting documentation of AR are provided in various BMDP technical reports. AR was used in determining the creep consolidation parameters.

BMDP Program 3R is identical to AR with the following exceptions: (1) the model function cannot be expressed as a system of coupled rate equations and (2) the response model derivatives are updated continuously during the regression. 3R was used to determine the flow potential parameters.

The input files required to execute an AR or 3R analysis are described in detail by Dixon et al. [1985] and in the BMDP Users' Digest [Hill, 1984]. The BMDP input files for the model fits are given in Appendix A.

4.5 RESULTS

This section presents the results of the model fits. The results are discussed in terms of the model parameters and the statistical measures defined in Section 4.3.

The crushed-salt constitutive model contains a total of 14 fitted parameters. Four of these parameters are termed the flow potential parameters (κ_0, κ_1, n, and D_v). These parameters were determined by fitting the crushed-salt constitutive model to the lateral-to-axial strain-rate ratios measured in the 18 shear consolidation tests. The remaining 10 parameters in the crushed-salt constitutive model are termed the creep consolidation parameters (η_0, η_1, n_f, a, p, n_s, r_1, r_3, r_4, and Q_s/R). Two sets of creep consolidation parameters were determined; namely, one set each resulting from fits to a database composed of 18 shear consolidation tests and to a combined database composed of the 18 shear and 40 hydrostatic consolidation tests. The parameters were determined by fitting the crushed-salt constitutive model to the axial and lateral strains measured

in each of the tests. The parameters η_0, η_1, and n_f define the stress measure σ_{eq}^f (Equation 2-3). Moisture dependence, grain-size dependence, and temperature dependence are defined by the parameters a, p, and Q_s/R, respectively (Equations 2-34 and 2-36). The remaining parameters (r_1, r_3, and r_4) are for the pressure-solutioning portion of the model (Equations 2-36 and 2-37).

4.5.1 Flow Potential Parameters

The flow potential parameters are given in Table 4-2. Plots of the predicted and measured lateral-to-axial strain-rate ratios as a function of density for each of the 18 shear consolidation tests are given in Appendix B.

Table 4-2. Flow Potential Parameters

Parameter	Magnitude	Units
κ_0	10.119	—
κ_1	1.005	—
n	1.331	—
D_t	0.896	—

4.5.2 Creep Consolidation Parameters

The creep consolidation parameters for each of the two model fits are given in Table 4-3. Plots of the predicted and measured lateral and axial strains for each of the 18 shear consolidation tests and 40 hydrostatic consolidation tests are given in Appendix C.

Table 4-3. Creep Consolidation Parameters (Page 1 of 2)

Parameter	Units	Shear Tests	Combined Tests
η_0	—	0.1029	0.0140
η_1	—	3.9387	3.3881
n_f	—	3.5122	3.9660
a	—	0.3147	$1.0(10^{-5})$
p	—	1.6332	1.0341

Table 4-3. Creep Consolidation Parameters (Page 2 of 2)

Parameter	Units	Shear Tests	Combined Tests
n_s	—	0.5576	1.5318
r_1	m^p·K/(MPa·s)	$1.041(10^{-6})$	$2.663(10^{-5})$
r_1^*	K/(MPa·s)	0.0194	0.3369
r_3	—	15.1281	0.1286
r_4	—	0.1678	0.1680
Q_s/R	K	1,077.46	2,897.08

r_1^* assumes grain size (d) = 1 mm and moisture content (w) = 1 %.

4.6 STATISTICAL MEASURES

4.6.1 Sum-of-Squared Error

The sum-of-squared error (SS_E) was calculated using Equation 4-6 for each of the model fits to the shear test database and the combined test database. Using these results and Equation 4-7, the normalized sum-of-squared error ($\overline{SS}_E$) was calculated for each of the model fits. These results are given in Table 4-4.

Table 4-4. Sum-of-Squared Error, SS_E

Test Database	SS_E	$\overline{SS}_E$
Shear	23.52	0.159
Combined	46.76	0.156

These results indicate that the model fit to the two databases are qualitatively about the same; i.e., about 16-% relative error.

4.6.2 Parameter Multicollinearity

The parameter correlation coefficient matrices for each of the model fits to the two databases are given in Tables 4-5 and 4-6. High parameter correlations ($>|\pm 0.9|$) are indicative of possible parameter multicollinearity. As pointed out in Section 4.3.2, high parameter correlations are indicative of either (1) deficiencies in the functional form of the crushed-salt constitutive model or (2) deficiencies (or gaps) in the test database.

In general, most of the parameter correlations are low ($<|\pm 0.9|$) for both fits. However, three sets of parameters in the fit to the shear test database ($a - p$, $r_3 - Q_s/R$, and $r_4 - Q_s/R$) and one set of parameters in the fit to the combined test database ($n_f - \eta_1$) have correlation coefficients greater than $|\pm 0.90|$. As discussed in Section 4.3.2, the shear test database parameter correlations were expected (cf. Equation 4-9).

The parameter correlation measure (pcm) and the average correlation coefficient ($\overline{c}$) were evaluated using Equations 4-11 and 4-12, respectively. These results are given in Table 4-7 for each of the model fits.

These results indicate that the parameters are slightly less correlated in the fit to the combined test database. However, the average correlation coefficient is less than $|\pm 0.5|$ in both fits, which indicates that the possibility of parameter multicollinearity is low.

4.6.3 Parameter Variation Among Fits

A quantitative measure of the parameter variation between the crushed-salt constitutive model fits to the two databases is defined in Section 4.3.3. The ratio simply indicates the magnitude of the change in each of the parameter values between the fits to the combined test database and the shear consolidation test database. The ratios of the parameter values from the two fits are given in Table 4-8. As can be seen in the table, parameters a, r_1, and r_3 varied by more than one order of magnitude (i.e., parameter ratio <0.1 or >10). This is a significant improvement over earlier work (e.g., Callahan et al. [1995]) where the parameter values were seen to change by several orders of magnitude between the different database fits. Qualitatively, the parameters did not change appreciably overall in the two model fits.

Table 4-5. Parameter Correlation Coefficient Matrix — Model Fit to Shear Consolidation Tests

	η_0	η_1	η_f	a	p	n_s	r_1	r_3	r_4	Q_s/R

r_4	0.4188	–0.3070	0.1607	–0.4692	0.3324	–0.3722	–0.4033	0.3078	1.0	
Q_s/R	0.1698	0.0489	–0.1124	–0.0133	–0.2102	0.2801	–0.0826	–0.5790	0.2697	1.0

The value for the exponent on moisture content, a, given in Table 4-3 for the combined database fit is 10^{-5}, which is the smallest value allowed during the fitting process. During the fitting, the value of a was driven to zero. In other words, the moisture function was driven to act like a Heaviside function turning the pressure solution portion of the model on and off, depending on whether or not moisture was present. However, when moisture content is zero (i.e., $w = 0$) and the exponent is zero, an indeterminate form is created. Thus, the value of the exponent a was limited to the small number to avoid the indeterminate form. Thus, the same conclusion is arrived at as discussed by Hansen et al. [1998] — no improvement in goodness of fit could be achieved by accounting for moisture variation once moisture was present. Further pertinent discussion on moisture is included in Chapter 6.0 of Hansen et al. [1998]. The other two parameter values exhibiting a significant change (r_1 and r_3) are also strongly correlated to the temperature parameter (Q_s/R) as shown in Tables 4-5 and 4-6. The combination of these three parameters can be examined with the function:

$$\chi(r_1,\ r_3,\ Q_s/R) = r_1 \exp\left(\frac{Q_s}{RT}\right) \exp(r_3 \epsilon_v) \tag{4-13}$$

Table 4-7. Parameter Correlation Measure

Test Database	pcm	$\bar{C}$
Shear	0.133	0.365
Combined	0.115	0.339

Table 4-8. Parameter Variation

Parameter	Parameter Set Ratio
η_0	0.14
η_1	0.86
n_f	1.13
a	0.00
p	0.63
n_s	2.75
r_1	17.37
r_3	0.01
r_4	1.00
Q_s/R	2.69

If a temperature of 298 K is assumed, the ratios of χ computed with the combined database parameters to the shear database parameters for volumetric strains of –0.10 and –0.15 are found to be 0.173 and 0.367. Thus, the combined effect of the significant change in the individual parameters is not significant. The cause of these changes is probably the lack of temperature variation in the shear consolidation database resulting in correlation of the parameter values. Overall, the change in parameter values from the two database fits is relatively minor.

4.6.4 Predictive Capability

The predictive capability of the crushed-salt constitutive model is measured qualitatively by how well the model fits to the shear consolidation tests are able to predict the hydrostatic consolidation tests. In other words, the shear consolidation test parameter values given in Table 4-3 were used to predict the hydrostatic consolidation tests with the goodness of fit determined by the sum-of-squared error. For comparison, the combined database parameter values given in Table 4-3 were also used to predict the same sets of tests. Different subsets of the hydrostatic tests were considered to see if the shear consolidation parameter values predicted any specific group of tests better than others. The hydrostatic test database subsets include: (1) dry (tests without any added moisture), (2) wet (test with added moisture), and (3) hydrostatic (the entire hydrostatic test database, including tests with and without added moisture). The sum-of-squared error was computed for each of these databases and are presented in Table 4-9. The shear and combined test databases are also included in Table 4-9 for comparison. Each of these databases exclude two tests: 29JAN82 and 26FEB82. These tests were excluded because they lie outside of the predictive range for the shear test-derived parameter values. This occurs because of the high mean stress and relatively low initial fractional densities for these two tests, which are outside of the shear test database. Table 4-9 shows that the shear test parameter set predicts the wet tests much better than the dry tests. Figures comparing the predicted results with the test data from the hydrostatic tests are given in Appendix C; specifically, Figures C-1 through C-40.

Table 4-9. Sum-of-Squared Error in Hydrostatic Consolidation Tests

Database Parameter Set	SS_E for Predicted Database				
	Shear	Dry[(a)]	Wet[(a)]	Hydrostatic[(a)]	Combined[(a)]
Shear	23.52	49.20	22.00	71.20	94.72
Combined	23.59	15.22	7.22	22.44	46.04

[(a)] Database excludes tests 29JAN82 and 26FEB82.

Upon visual examination of Figures C-1 through C-4, the shear database parameter value set appears to predict the dry tests better than the combined database parameter value set. However,

examination of Figures C-17 to C-28 shows that the model fit to the shear test database does not predict the hydrostatic tests that are dry very well, particularly as the mean stress increases. As can be seen in Table 4-9, the sum-of-squared error from predicting the wet hydrostatic tests (22.00) is about the same as the combined database parameter set fit to all of the hydrostatic tests (22.44).

These results suggest that the crushed-salt constitutive model (with parameter values determined from the shear consolidation tests) has reasonable predictive ability. As evidenced in Table 4-9, the model predicts the wet hydrostatic tests nearly as well as the model fits all of the hydrostatic tests. However, since the shear consolidation test database only includes two dry tests, the prediction of the dry hydrostatic consolidation tests is not as good. As further evidenced in the figures in Appendix C, visual comparison of the two fits shows qualitative sameness, even though the parameter values themselves might appear to be quite different (Table 4-3). The model contains both a volumetric (hydrostatic) component and a deviatoric (shear) component, both of which are present in the shear consolidation tests. Thus, the model not only characterizes (fits) the shear data well, it can reproduce (predict) simpler conditions nearly as well. This provides strong evidence that the model has the potential for predicting the consolidation of crushed salt in other, more complex, conditions as well, including the behavior of the shaft seal. This is explored further in Chapter 5.0, which presents the model predictions of constant strain-rate tests.

5.0 MODEL VERIFICATION

After a material model has been developed, the question remains as to how well it represents real-world problems. Constitutive model verification is best accomplished through the prediction of carefully conducted in situ experiments. When these in situ experiments do not exist, confidence in the model and partial verification can be accomplished by predicting bench-scale and other laboratory tests outside of the database upon which the model development relied. This was demonstrated in Chapter 4.0 where the shear consolidation parameter value set was used to predict the hydrostatic consolidation tests. In this chapter, model verification is pursued further by predicting three constant strain-rate tests using both the shear and combined database parameter value sets. The constant strain-rate tests provide an excellent verification test of the constitutive model since these tests provide a constant strain-rate and varying stress rate; whereas, the constitutive model was developed based on tests that included a constant stress and a varying strain rate. Since the constant strain-rate tests were not included in the model fitting database and represent a totally different load path than the creep consolidation tests, they are ideal for testing the predictive ability of the constitutive model.

5.1 DESCRIPTION OF CONSTANT STRAIN-RATE TESTS

Three constant strain-rate tests were performed on laboratory-scale specimens. The specimens were dynamically compacted using the same technique and raw crushed-salt materials that were employed for fabrication of the shear consolidation specimens. Thus, the constant strain-rate specimens had nominal lengths of 200 millimeters, nominal diameters of 100 millimeters, and nominal fractional densities of 0.9. All three tests were performed at a confining pressure of –1 MPa, a temperature of 20°C, and a constant axial strain rate. Essentially, the test procedure included applying a –1 MPa confining pressure, monitoring the axial strain rate, and initiating the constant axial strain rate when the monitored rate was less than the targeted test axial strain rate. The constant axial strain rate was different for each test, as shown in Table 5-1.

Specimen RS/DCCS/6 was used to perform the first constant strain-rate test on crushed salt, and this first test served to refine the test procedure as stated above. The first two attempts at performing this test were aborted, but the third attempt was successful. The first attempt was aborted because the constant strain-rate phase of the test was entered before the consolidation rate in the preceding hydrostatic phase had slowed to a value less than -1×10^{-7} s^{-1}. This caused

the test system to unload. The second attempt was aborted by failure of an electronic power supply in the test system shortly after the constant strain-rate phase had begun. After determining new specimen dimensions (there was some deformation induced during the first two aborted attempts), a third attempt was successful. At the start of the third attempt, the specimen had a length of 190.3 millimeters, a diameter of 101.6 millimeters, and a fractional density of about 0.92. The test duration was about 1 week, and the controlled test variables were maintained. The radial strain rate was initially compressive and eventually changed sign and became extensile as the specimen density increased. The other two constant strain-rate tests, RS/DCCS/11 and RS/DCCS/21, were performed without incident at axial strain rates of one-half and double, respectively, the strain rate used for RS/DCCS/6. Additional details of the constant strain-rate test equipment, procedures, and results can be found in Mellegard et al. [1999].

Table 5-1. Test Matrix for Constant Strain-Rate Experiments

Specimen I.D.	Initial Fractional Density	Axial Strain Rate (10^{-7} s^{-1})	Confining Pressure (MPa)	Temperature (°C)
RS/DCCS/11	0.912	–0.5	–1	20
RS/DCCS/6	0.921	–1.0	–1	20
RS/DCCS/21	0.907	–2.0	–1	20

5.2 PREDICTION OF CONSTANT STRAIN-RATE TESTS

The crushed-salt constitutive model described in Chapter 2.0 was incorporated into the thermomechanical finite element stress analysis program SPECTROM-32 [Callahan et al., 1989], Version 4.10. Thus, prediction of the constant strain-rate tests was performed using the finite element program with one element. For each test simulation, an element was initially subjected to the time-weighted average axial and lateral stress conditions realized in each test. The stress condition was designed to be a hydrostatic load of –1 MPa; however, the actual test conditions achieved were slightly different than the design condition. The stress conditions were maintained for the *hydrostatic* duration realized in the tests. Then, time-weighted average, time-wise kinematic boundary conditions were applied to the element that matched the constant strain-rate conditions achieved in the tests. The actual time-weighted test conditions for confining pressure

and axial strain rate, as well as the duration of the hydrostatic phase for each of the tests, are given in Table 5-2.

Table 5-2. Time-Weighted Average Test Conditions for Constant Strain-Rate Experiments

Specimen I.D.	Hydrostatic Duration (s)	Axial Stress (MPa)	Lateral Stress (MPa)	Axial Strain Rate (10^{-7} s^{-1})
RS/DCCS/11	93,150	–1.025	–0.998	–0.504
RS/DCCS/6	13,127	–0.999	–0.987	–1.008
RS/DCCS/21	55,870	–1.047	–0.985	–2.040

Thus, the constant strain-rate test simulations used the average actual test conditions. Simulations were performed using both the shear database and combined database parameter sets given in Table 4-3.

Axial and lateral strain simulation results obtained for the three constant strain-rate tests are shown in Figures 5-1 through 5-3 plotted with the laboratory data.

Predicted results are shown for the two different parameter value sets given in Table 4-3. In all three figures, the axial and lateral strain simulation results reproduce the laboratory data reasonably well; however, an offset is noticeable in the strains that appears to be generated by the hydrostatic portion of the tests. The laboratory data exhibit a curious lateral and axial strain response during the presumed hydrostatic portion of the tests. Normally, one would expect the axial and lateral strain to be the same during hydrostatic compression of a homogeneous material. However, the axial and lateral strains are noticeably different in all three of the constant strain-rate tests during the hydrostatic loading phase of the tests. There are three possible explanations for this anomalous behavior related to (1) stress difference, (2) other modes of deformation, and (3) specimen inhomogeneity. Each of these items is briefly discussed separately.

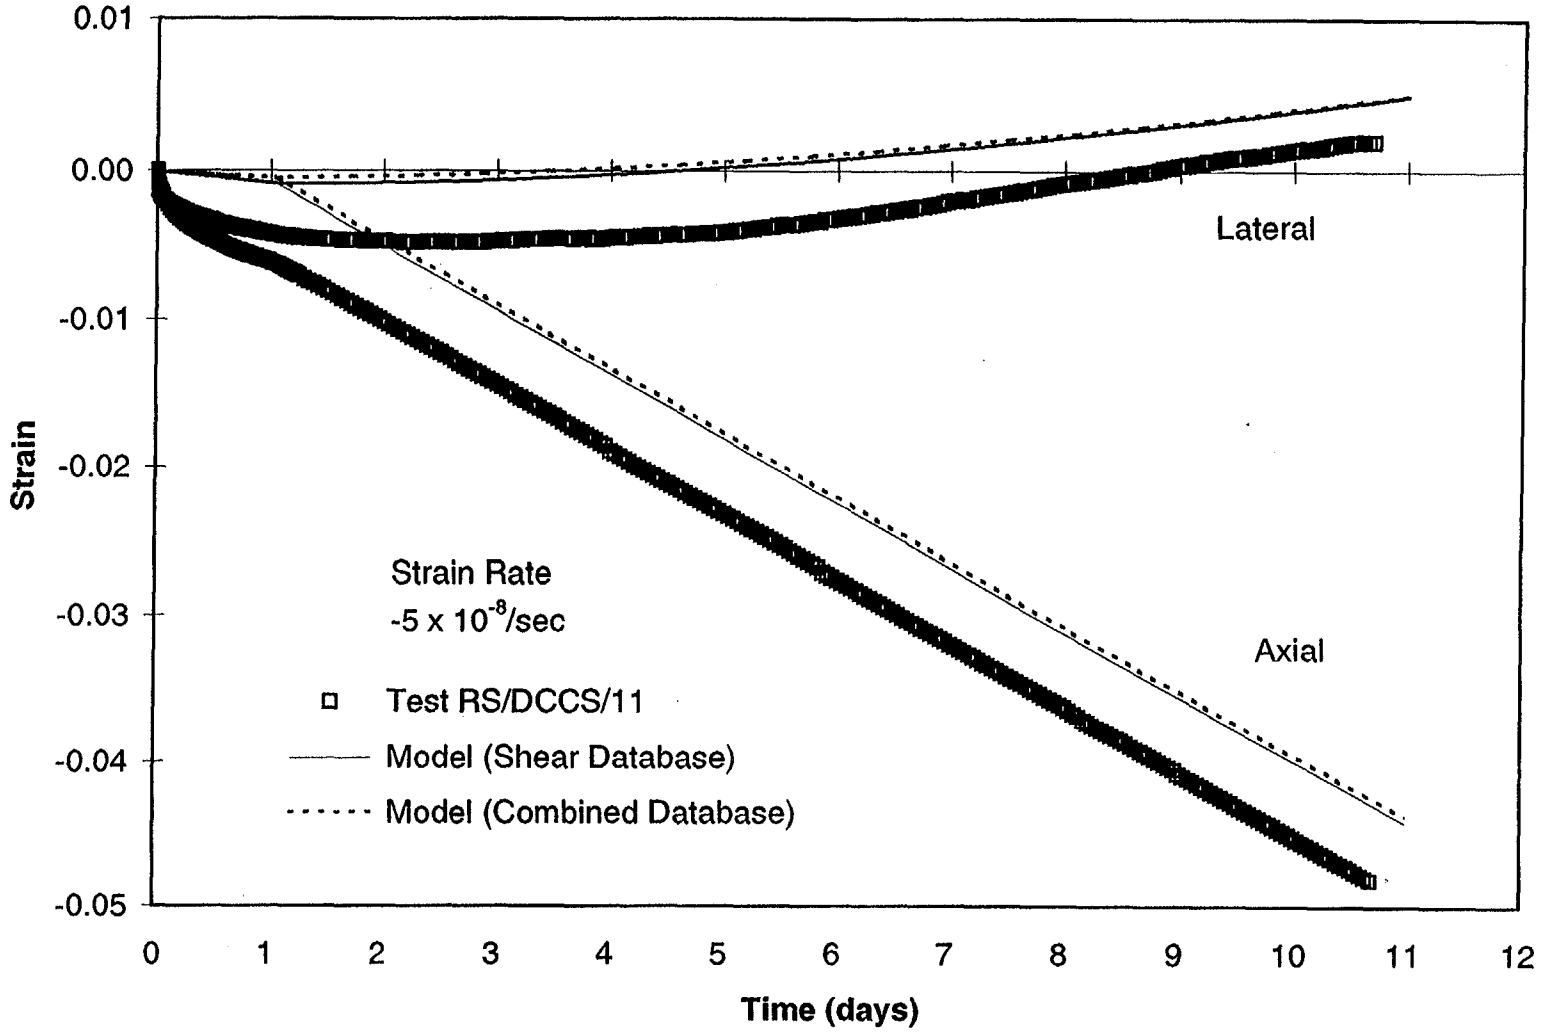

Figure 5-1. Comparison of predicted strains and laboratory data for test RS/DCCS/11 ($-0.5 \cdot 10^{-7} s^{-1}$).

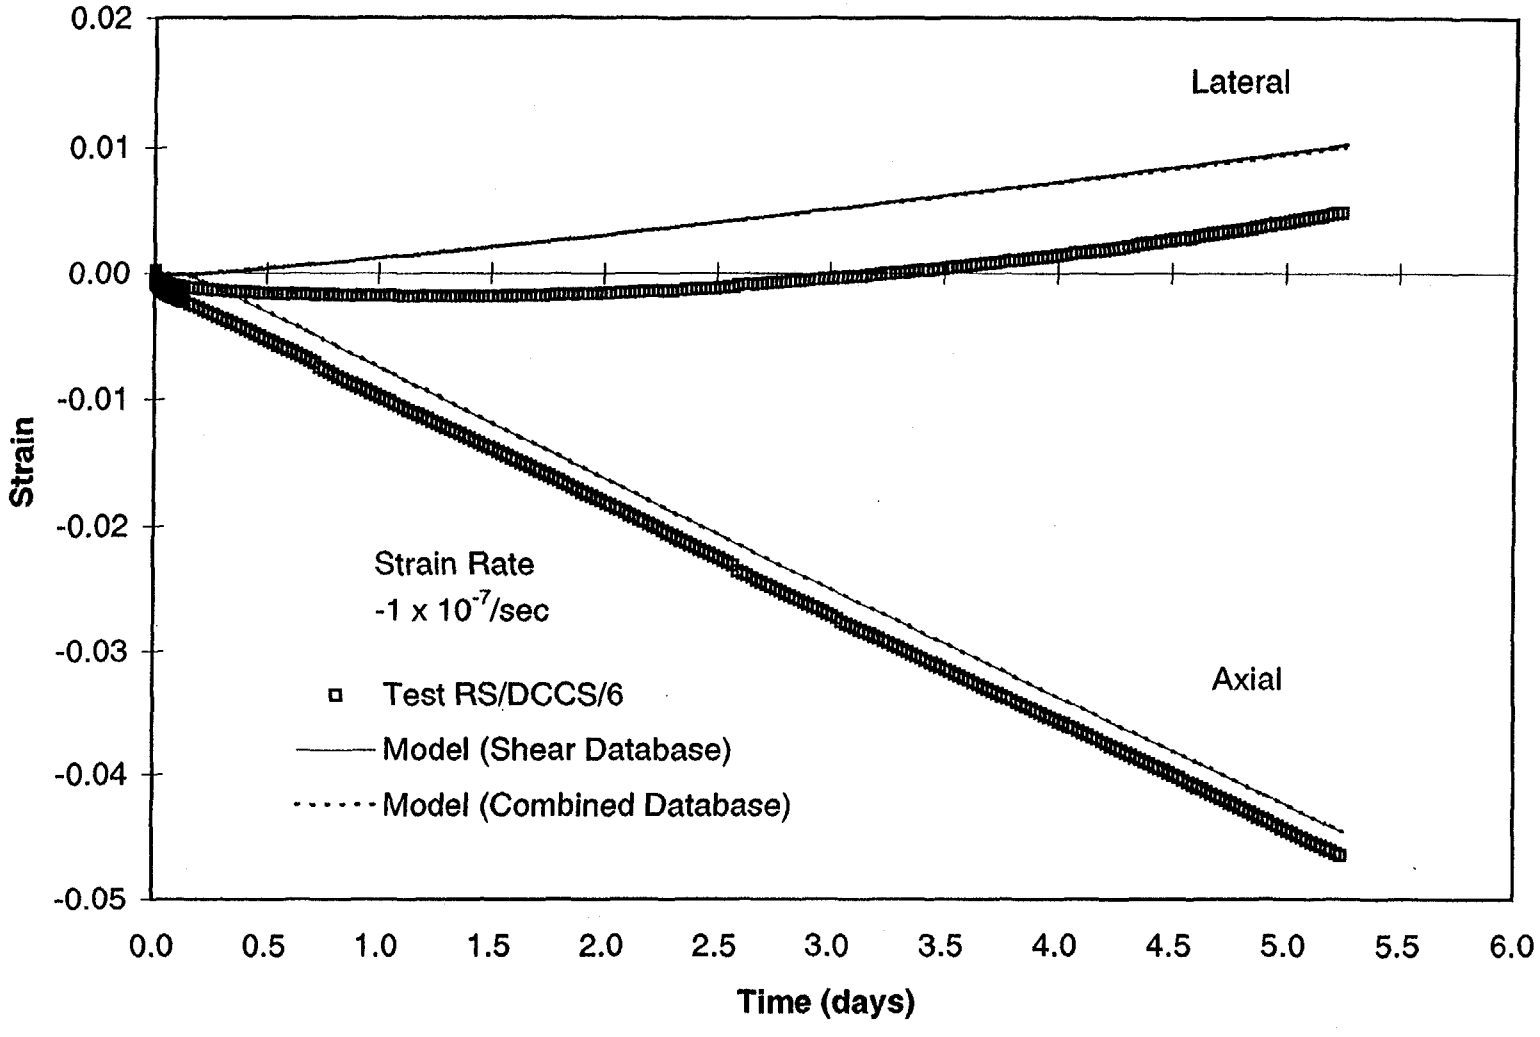

Figure 5-2. Comparison of predicted strains and laboratory data for test RS/DCCS/6 ($-1.0 \cdot 10^{-7} s^{-1}$).

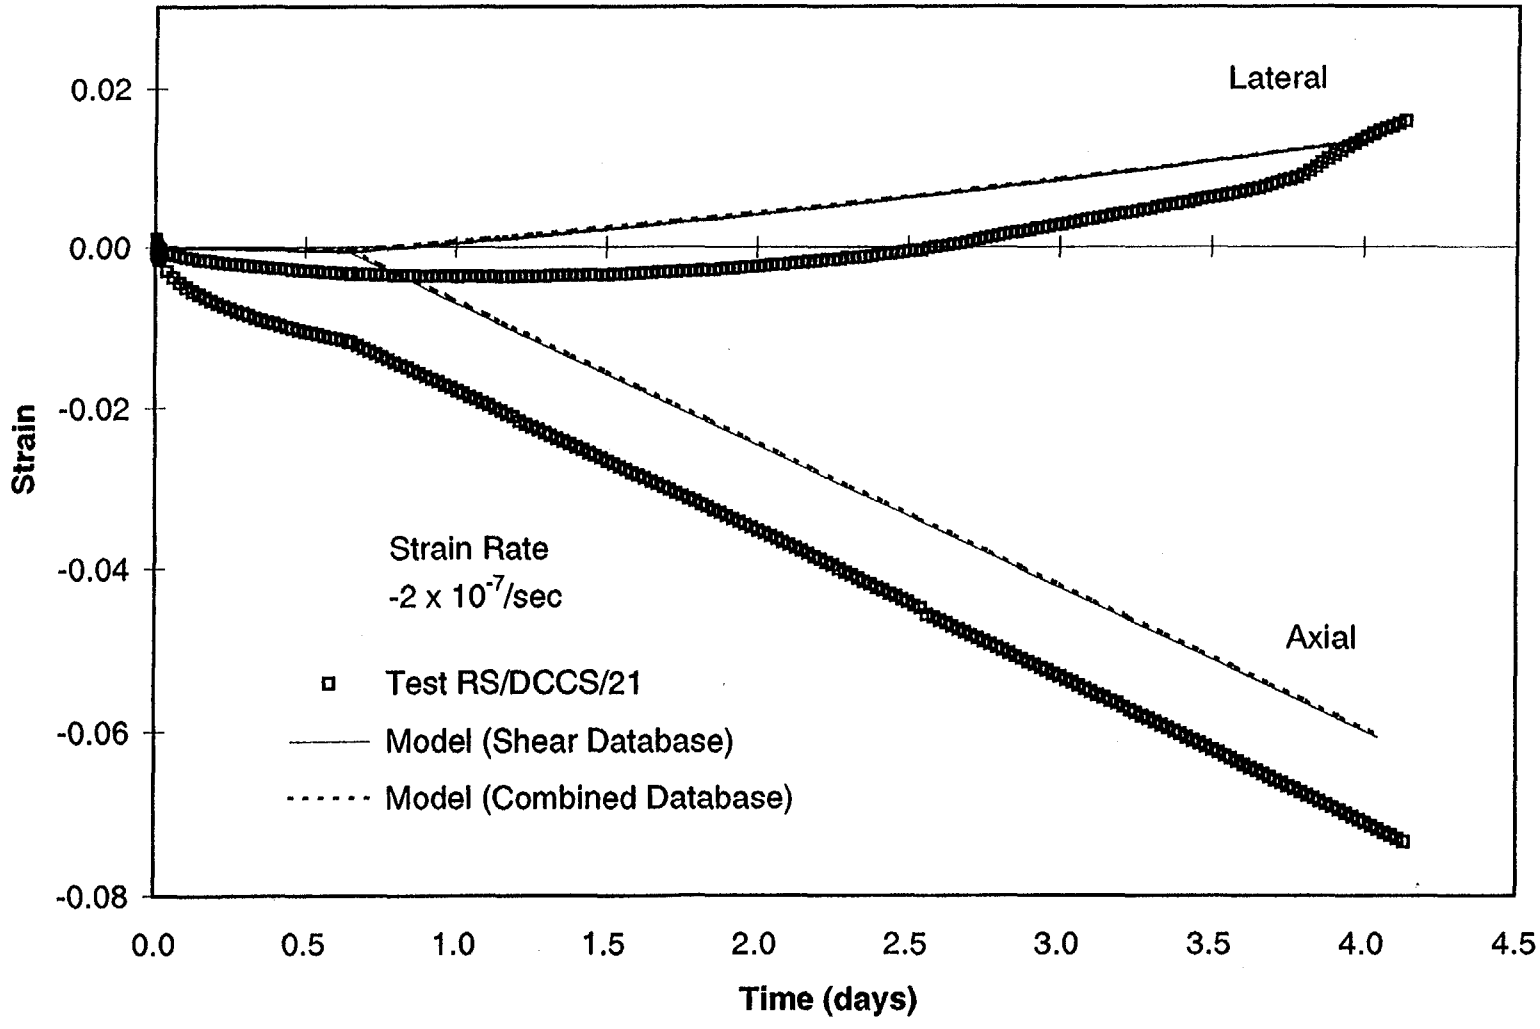

Figure 5-3. Comparison of predicted strains and laboratory data for test RS/DCCS/21 ($-2.0 \cdot 10^{-7} s^{-1}$).

Stress Difference: As given in Table 5-2, the actual axial and lateral stresses applied during the *hydrostatic* portion of the test are not equal as desired. In all three tests, the time-weighted average axial stress is greater than the lateral stress. However, the largest stress difference is only 0.0619 MPa for Test Specimen RS/DCCS/21. While this stress difference contributes to the larger axial strains, it does not appear to be large enough to be solely responsible for the differences in axial and lateral strains. This judgment is made based on the predicted test results which show almost no difference between the axial and lateral stresses. The constitutive model predicts the shear consolidation tests reasonably well; however, these tests involve larger stress differences. This leads one to believe other factors are involved in the axial and lateral strain differences.

Deformation Modes: Upon loading the specimen, there is a certain amount of cataclastic deformation and sliding along the particle interfaces. These deformation mechanisms could create axial and lateral strain differences, which would be amplified by the stress difference.

Specimen Inhomogeneity: Preparation of the dynamically compacted crushed-salt specimens is discussed in detail by Mellegard et al. [1999]. Basically, a laboratory-scale compaction device that approximates the envisioned shaft seal compaction method was used to fabricate the specimens. The specimens were fabricated in three lifts, which created layers of finely pulverized salt about 10 millimeters thick at one-third and two-thirds of the specimen height. These bands of fines, perpendicular to the specimen axis, form significant specimen inhomogeneities that may have contributed to the anisotropic deformation behavior of the specimens. These bands would not affect the axial deformation significantly but could have acted as stiffeners restricting the lateral compaction of the specimens.

With the data available, the importance of these three factors' impact on the specimen deformation cannot be quantified. All three factors may be contributing to the observed deformation behavior of the specimens.

Figures 5-4 through 5-6 plot only the constant strain-rate portion of the tests. This portion of the test begins after the hydrostatic portion ends, as given in Table 5-2. In Figures 5-4 through 5-6, the axial and lateral strains and time have been translated so that the values are all zero at the beginning of the constant strain-rate portion for each test. These results show that the simulation results reproduce the laboratory data quite well. Of course, the axial strain rate is an imposed condition that should be reproduced exactly, and the fact that the axial strain simulation results overlay the axial laboratory data provides a check that the correct strain rate was used in the simulations. Figures 5-7 through 5-9 plot the lateral strains only for the constant strain-rate portion of the tests so that comparison of the computed results and laboratory data can be made

more readily. These figures show decreasing agreement between computed results and laboratory data as the strain rate increases. However, the prediction of the lateral strains is still quite good even at the highest strain rate when one considers the fact that both the test data and load path for the constant strain-rate tests are outside of the database upon which the constitutive model parameters are based. Figures 5-1 through 5-9 show minor differences between the predicted results for the shear and combined database parameter value sets even though some of the parameter values in the two sets appear to be quite different.

The predicted axial stress results for the three constant strain-rate tests are compared in Figures 5-10 through 5-12. The lateral stresses (or confining pressures) are constant throughout the duration of the tests at the values given in Table 5-2. The predicted stress magnitudes are in the range of the laboratory results but consistently over predict the laboratory data following application of the constant strain rate. The over prediction is amplified as the constant strain rate increases. The discontinuities in the axial stress measurement were traced back to a test system control problem, as discussed by Mellegard et al. [1999]. This problem was eliminated, but not until after all three constant strain-rate tests had been conducted. As seen in Figures 5-10 through 5-12, the laboratory measured axial stresses do not increase significantly as the strain rate increases, despite RS/DCCS/21 strain rate being four times that of RS/DCCS/6; whereas, the increase of the predicted axial stresses is significant with increasing strain rate. A rapid rise in axial stress is seen in each of the test simulation results following application of the constant strain rate. There are undoubtedly cataclastic deformation mechanisms operative in these crushed-salt specimens. These mechanisms, which are not included in the crushed-salt constitutive model, are most likely responsible for the moderate stress rises observed in the laboratory tests as compared to the rapid rise in the stress seen in the predictions.

The numerical prediction of the constant strain-rate tests shows that the crushed-salt constitutive model is able to predict the strains quite well. The prediction of the stresses is not as good as the strain predictions and indicates that deficiencies remain in the model. These deficiencies are believed to be embodied in the lack of cataclastic deformation mechanisms in the model. However, the importance of the cataclastic deformation will not be as important in the actual crushed-salt seal components where the strain rates will be more than an order of magnitude less than the slowest strain rate used in the laboratory tests.

6.0 SHAFT SEAL CALCULATIONS

The current seal designs for the WIPP specify the emplacement of various materials (asphalt, compacted clay, concrete, and crushed salt) in the shafts from the earth's surface to the repository horizon. Crushed salt will be emplaced within the shafts at depths ranging from 430 meters to 600 meters and dynamically compacted to a fractional density of about 0.9. The flow characteristics of the crushed-salt seal are of primary importance since the long-term function of the seal is to prevent the flow of water into the repository from overlying aquifers and to prevent the flow of gas out of the repository. Closure of the shaft resulting from creep of the surrounding intact salt will consolidate the crushed salt over time. The consolidation process reduces the permeability of the crushed salt from its emplaced state to its intact state, creating an effective long-term seal.

The purpose of this chapter is to demonstrate the creep consolidation behavior of a typical crushed-salt shaft seal problem using the model and material parameter values described in Chapters 2.0 and 4.0. The problem selected is identical to the one presented by Loken [1998]. In this earlier study, Loken [1998] compared the combined-mechanism, crushed-salt constitutive model shaft seal simulation results using material properties from Hansen et al. [1998] to shaft seal simulation results obtained using three earlier candidate crushed-salt constitutive models described by Callahan et al. [1995]. Thus, the results obtained in this chapter are compared with the results generated by prior versions of the crushed-salt model.

6.1 SHAFT PROBLEM DESCRIPTION AND ASSUMPTIONS

The shaft configuration chosen to demonstrate the crushed-salt seal behavior is the simplest configuration that can be used to evaluate the seal system. The model is an axisymmetric representation of the shaft and host rock at a fixed depth. By changing the initial stress and temperature conditions, different depths may be examined. The following assumptions apply to the selected model and govern the simulation procedure:

- A condition of plane strain is assumed to exist with respect to the axial (vertical) direction.
- The stratigraphy at the WIPP is ignored. The intact salt surrounding the shaft is assumed to be composed entirely of argillaceous salt governed by the multimechanism deformation creep fracture (MDCF) model [Chan et al., 1998].
- The initial stress state before shaft excavation is lithostatic.
- The shaft is excavated into the lithostatic stress field at time zero.
- The shaft is assumed to be open for 50 years and then instantaneously filled with crushed salt dynamically compacted to a fractional density of 90-%.
- The weight of the crushed-salt backfill is ignored.

- The shaft is assumed to be sufficiently isolated to exclude the influence from other excavations and shafts.
- The deformation and strains predicted during the simulation period are sufficiently large such that finite strain analysis is required.

Figure 6-1 provides a schematic representation of the shaft seal problem. The radius of the shaft was taken as unity, and the outer boundary was placed at 100 radii to be far enough removed so as not to influence the results. For time $t < 0$ years, the shaft is not present and an initial lithostatic stress field exists in the host rock such that the three principal stresses are identical. At time $t = 0$ years, the cylindrical shaft is excavated and the surrounding host salt formation creeps into the shaft for a period of 50 years. At time $t = 50$ years, crushed salt with an initial density of 1,944 kg/m^3 (90-% of intact salt density) is emplaced within the shaft. The salt surrounding the shaft continues to creep and transfers load to the crushed-salt seal, causing the crushed-salt to consolidate. The total simulation period is 500 years.

A representative depth of 550 meters is used to compare the results predicted by the crushed-salt combined mechanism model with those predicted using previous models. Three additional depths (430 meters, 515 meters, and 600 meters) are used to illustrate the magnitude of consolidation as a function of depth for the combined mechanism model. Temperature and initial stress conditions consistent with the host rock at the four depths considered in the calculations are given in Table 6-1.

6.2 MATERIAL MODELS AND PARAMETER VALUES

Two types of material models are required to solve the shaft seal problem based on the problem definition given in Section 6.1. Material models include: (1) a material model to describe the creep behavior of the host salt formation and (2) material models to describe the consolidation of the crushed-salt seal material. The host salt material model used for all of the comparative analyses was the same so that differences in the material models used for the crushed-salt seal could be observed. In all of the crushed-salt consolidation models, the average grain size and moisture content was assumed to be 1 millimeter and 1-% by weight, respectively. The constitutive models used in this study are described briefly in Section 6.2.1.

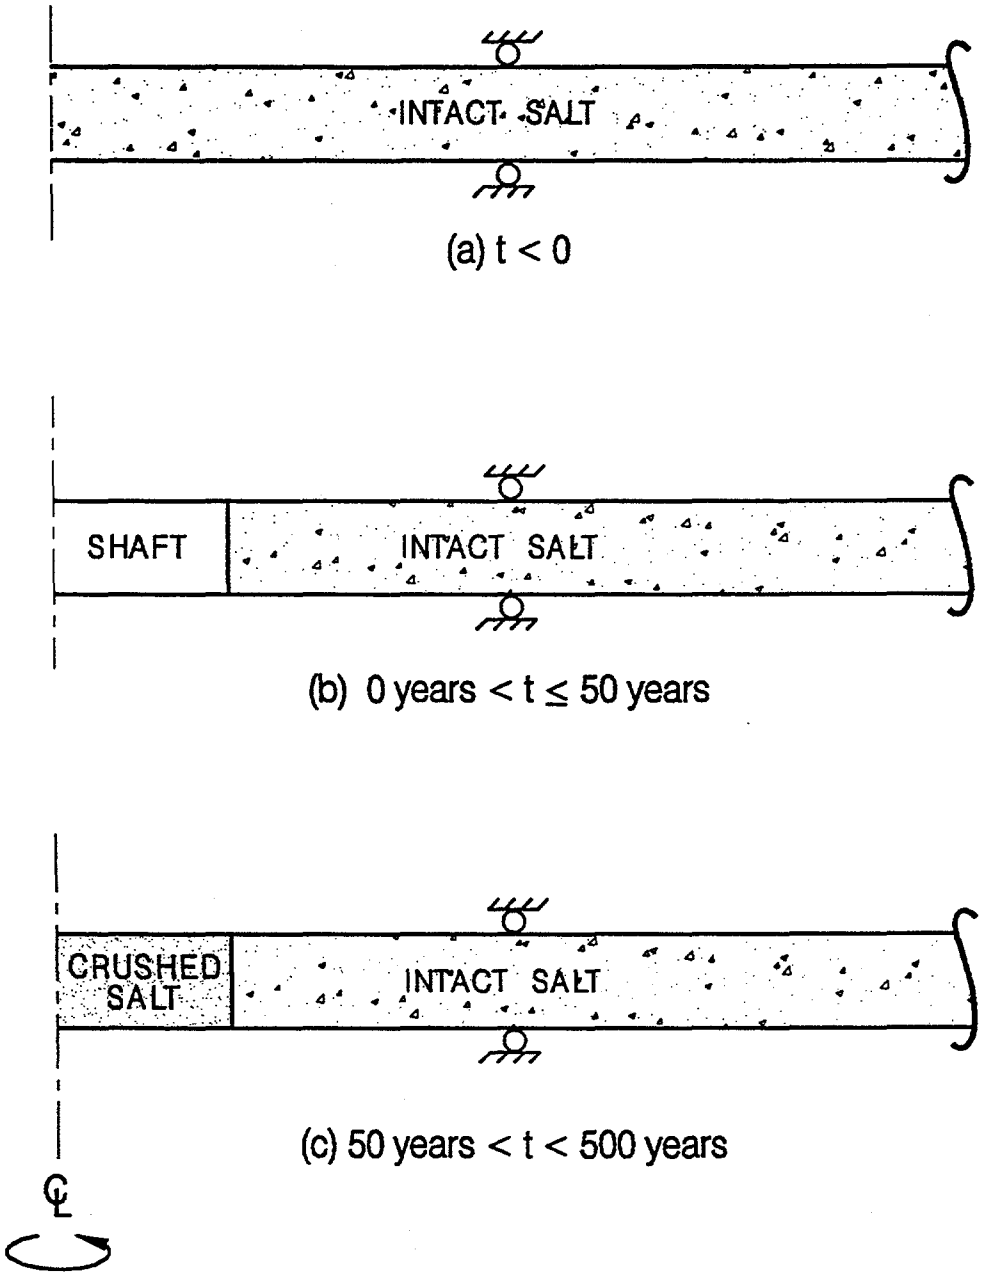

Figure 6-1. Schematic representation of the shaft seal problem.

6.2.1 Intact Salt Model

The material behavior of intact salt was modeled using the MDCF model for argillaceous halite. A description of the MDCF model is given by Chan et al. [1998], along with associated parameter values for WIPP argillaceous salt. Loken [1998] provides additional discussion of the parameters used in the analyses. The same intact salt model was used regardless of the constitutive model used to represent the crushed-salt seal. Thus, the host salt formation's driving force on the seal was identical in all analyses until host salt-seal interaction became important.

Table 6-1. Initial Temperature and Stress Conditions at WIPP for Various Depths within the Salado Formations

Depth (m)	Initial Conditions	
	Temperature[a] (°C)	Stress[b] (MPa)
430	24.8	9.85
515	25.65	11.76
550	26.0	12.57
600	26.5	13.68

[a] Based on a temperature of 27° at 650-m depth and a geothermal gradient of 10°C/km [Sass et al., 1971].

[b] Based on an in situ stress of 14.8 MPa at 650-m depth [Bailey et al., 1992] and an average overburden density in the Salado Formation of 2,300 kg/m^3 [Krieg, 1984].

6.2.2 Previous Consolidation Models

Loken [1998] used parameter values derived from an earlier crushed-salt database and compared the combined-mechanism crushed-salt model results to those obtained from three earlier creep consolidation models developed for crushed salt. These three earlier creep consolidation models are described by Callahan et al. [1995] and include the modified Sjaardema-Krieg model, the modified Zeuch model, and the modified Spiers model. The Sjaardema-Krieg model is an empirical model. The Zeuch model was derived from a hot-isostatic pressing model for dry crushed salt. The Spiers model is a grain boundary diffusional pressure solution model, appropriate for wet crushed salt. The parameter values that define each of these models are given by Callahan et al. [1998a]. Each of these models also contain a nonlinear elastic model proposed by Sjaardema and Krieg [1987] and described by Callahan et

al. [1995]. Mellegard et al. [1999] show reasonable agreement of additional test data compared with the bulk modulus functional form used by Sjaardema and Krieg [1987]. Finally, each of the creep consolidation models contain a Munson-Dawson (M-D) deviatoric portion using the parameter values given in Table 4-1.

6.2.3 Combined Mechanism Model

The combined mechanism model comprises two mechanisms, dislocation creep and grain boundary diffusional pressure solution, and is described in detail in Chapter 2.0. The same nonlinear elastic model is used with this model as described for the previous consolidation models. Three different sets of parameter values were used for the combined mechanism model for analyses of the shaft seal problem. The first set of parameters, reported by Hansen et al. [1998], was determined from the least-squares fit to the database that includes both the shear and hydrostatic consolidation tests but excludes the recent tests discussed in Chapter 3.0. The results of the shaft analyses using these parameter values are documented in Loken [1998]. The other two sets of parameter values, used in the current analyses, are given in Table 4-3 and are referred to as the *shear parameters* and *combined parameters*. The flow potential parameter values are given in Table 4-2.

6.3 CALCULATION RESULTS

Finite element program SPECTROM-32 [Callahan et al., 1989], Version 4.10, was used to predict the creep deformation of the host rock and the consolidation of the crushed-salt seal material. The finite element model used in solving this problem comprises a single row of 51 isoparametric elements. Fifteen elements were used to represent the shaft and 36 elements were used to model the surrounding intact salt. The outer boundary condition consisted of a constant traction boundary condition consistent with the initial stress level for each respective depth analyzed. Kinematic constraints were applied along the horizontal boundaries to prevent axial displacements.

Eight shaft seal analyses were performed, which resulted from using the shear and combined parameter values sets for the combined mechanism model at each of the four depths. The results of these eight calculations are compared with the results of Loken [1998] for shaft analyses using the modified Sjaardema-Krieg, modified Zeuch, and modified Spiers consolidation models and the combined mechanism model with a different combined database parameter value set. Figure 6-2 presents a comparison of the fractional densities predicted by four creep consolidation models at a depth of 550 meters.

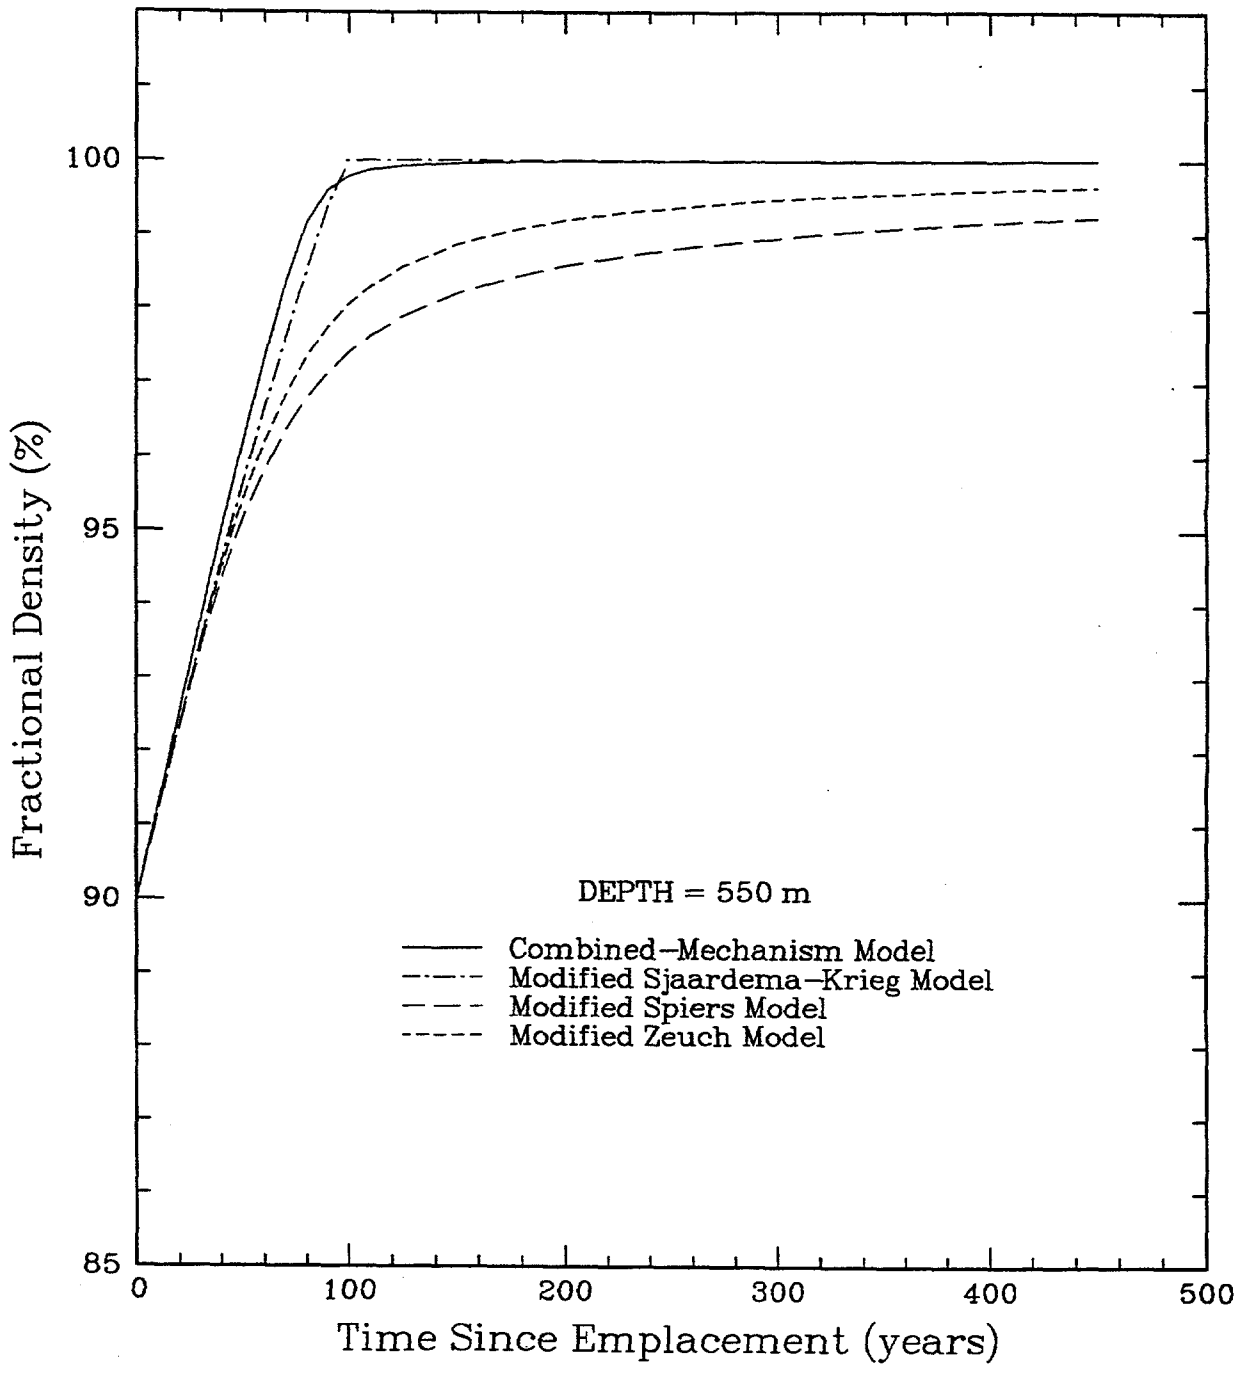

Figure 6-2. Comparison of four creep consolidation models for prediction of crushed-salt fractional density as a function of time at a depth of 550 meters.

These results indicate that the responses are similar for all four models up to a fractional density of 95-%. For this representative depth, approximately 50 years are required to consolidate the crushed salt from 90 to 95-% for all four models. At higher fractional densities, the model results diverge. The results shown in this figure also indicate that the combined mechanism model predicts the fastest consolidation rate when the fractional density is less than 98-%. A relative ranking of the four models in terms of their predicted consolidation rates (from fastest to slowest) is: (1) the combined mechanism model, (2) the modified Sjaardema-Krieg model, (3) the modified Zeuch model, and (4) the modified Spiers model. The results show that the predicted fractional density is nearly a linear function of time for the modified Sjaardema-Krieg model; whereas, the responses of the combined mechanism, modified Zeuch, and modified Spiers models are nonlinear. The Sjaardema-Krieg model predicts full consolidation within 100 years; the other models do not predict that the crushed salt will reach the density of intact salt during the 450-year simulation period following emplacement of the crushed salt. This occurs because the empirical Sjaardema and Krieg model does not stop consolidating when the density of intact salt is reached. The consolidation is simply stopped numerically when the fractional density reaches 100-%.

For comparison, the times required to achieve fractional densities of 92, 94, 96, and 98-% for all four models are given in Table 6-2. Table 6-2 also includes the associated times predicted by the combined mechanism model using the parameter estimates obtained from the fit to the database consisting of 18 shear consolidation tests.

Table 6-2. Time (Years) Required to Reach Fractional Densities for Four Consolidation Models at a Depth of 550 Meters

Fractional Density (%)	Combined Mechanism Model		Modified Sjaardema-Krieg Model	Modified Zeuch Model	Modified Spiers Model
	Shear Parameters	Combined Parameters			
92	16	16	17	17	17
94	32	32	35	35	37
96	49	49	55	57	65
98	67	66	75	100	135
100	—	—	100	—	—

Figure 6-3 shows the calculated fractional densities as a function of time at depths of 430, 515, and 600 meters using the combined mechanism model with the three different parameter sets. The results indicate that the crushed salt will reach 99-% of the density of intact salt within 300 years after emplacement, regardless of depth. The transition from deformation dominated by grain boundary diffusional pressure solution to dislocation creep at very high fractional densities (fractional densities greater than 99-%) is slower for the current parameter estimates than those predicted by Loken [1998] with an earlier derived combined database parameter set.

Figure 6-3 shows that the consolidation rate using the shear and combined test parameters deviates from Loken's results at a fractional density of approximately 98-%. As a result, the time required to consolidate crushed salt to the density of intact salt (fractional density of one) is greater for the shear and combined test parameter values than Loken [1998] computed. Specifically, the times predicted by the combined mechanism model to reach the density of intact salt at a depth of 600 meters are approximately 60 years and 170 years for the Loken [1998] calculations and shear test parameter values, respectively; whereas, the new combined test parameters did not predict full consolidation during the 450-year simulation period. Similar differences are observed at the shallower depths, as illustrated in Figure 6-3.

Figure 6-4 illustrates the time to reach 99.9-% of the intact density of salt predicted by the combined mechanism model as a function of depth for the three parameter sets. As shown in this figure, the time to compact the crushed salt is a nonlinear function of depth. The difference in the model predictions illustrated in this figure is caused by the different consolidation rates determined by the combined mechanism model for fractional densities greater than 98-%. For fractional densities less than 98-%, all models consolidate at approximately the same rate for a given depth, with higher consolidation rates calculated at greater depths as shown in Figure 6-3.

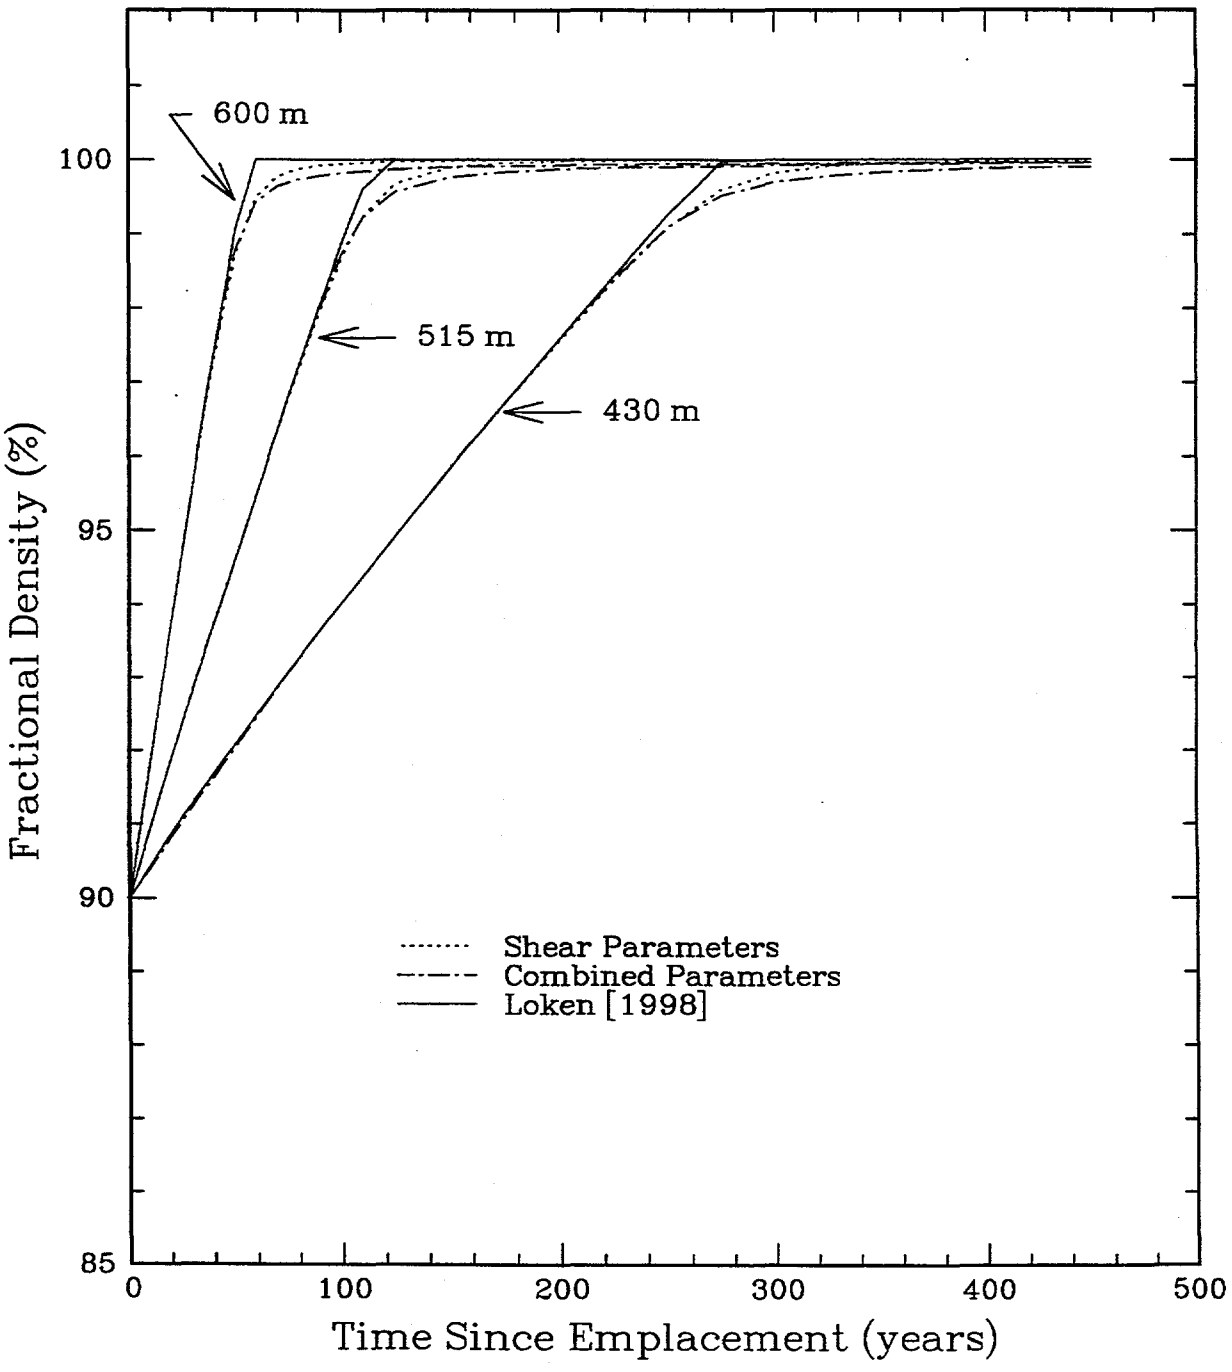

Figure 6-3. Fractional density as a function of time at depths of 430, 515, and 600 meters using the combined mechanism model.

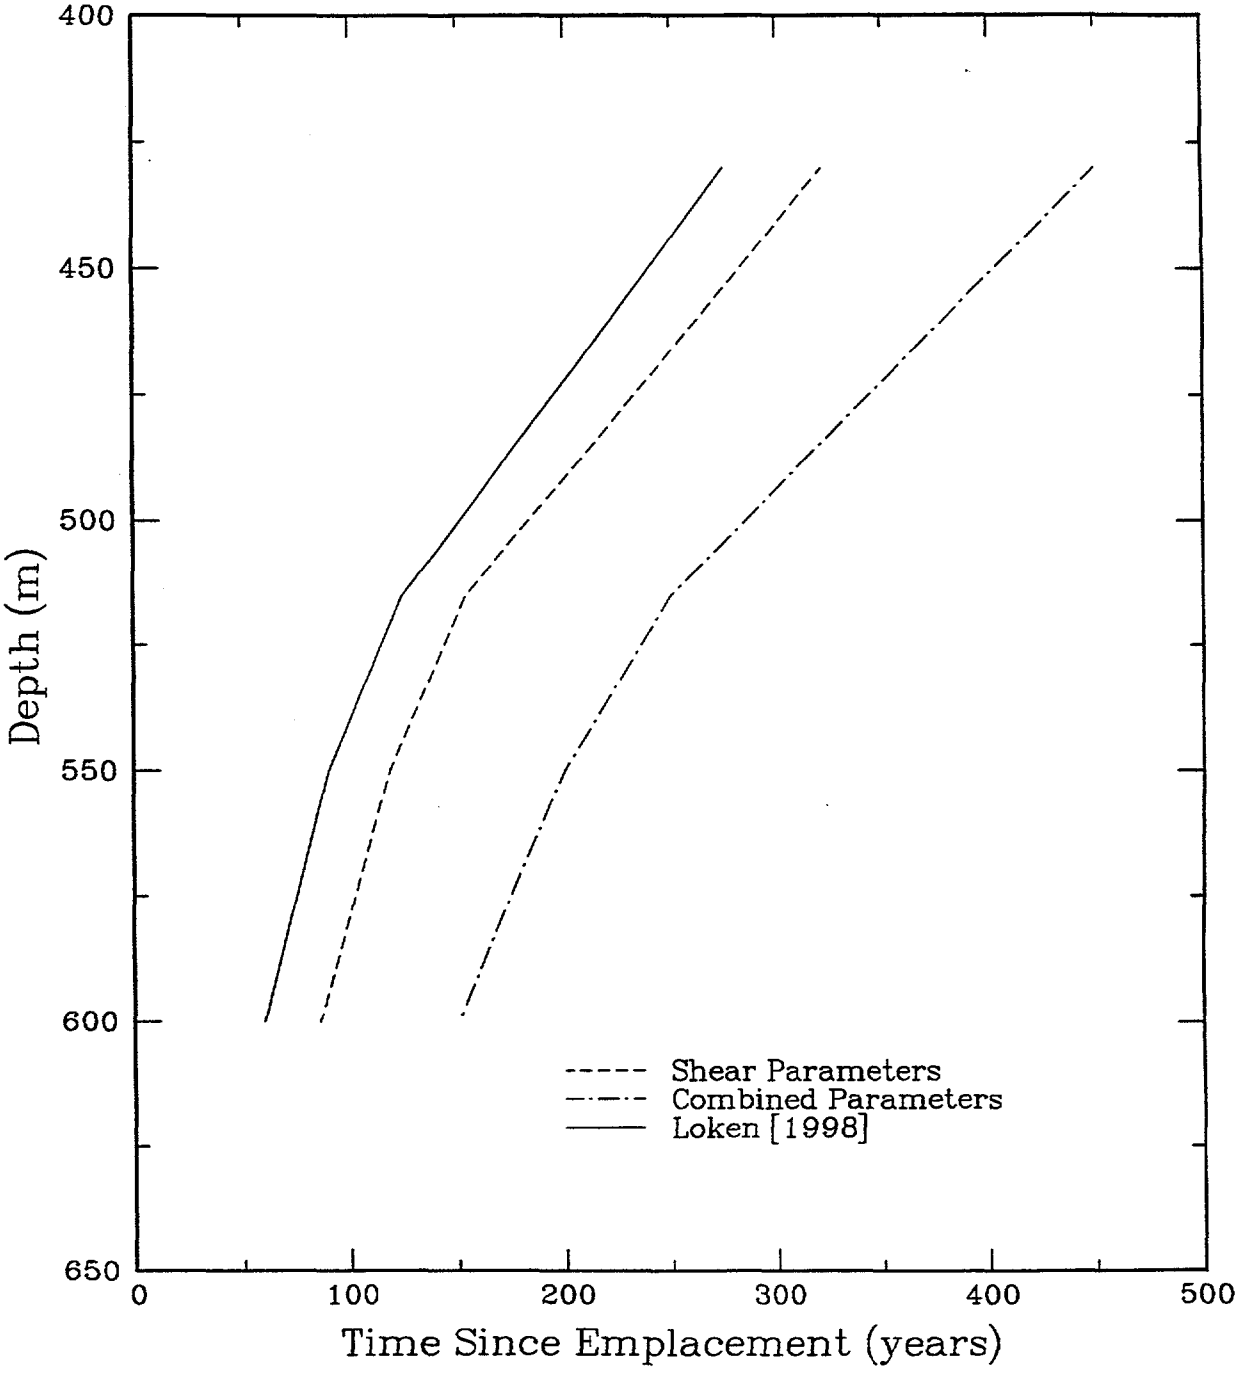

Figure 6-4. Time to consolidate to 99.9 percent fractional density as a function of depth using the combined mechanism model.

In summary, the consolidation rates predicted by the combined mechanism model for a shaft seal problem are nearly the same using the shear and combined parameter values as those predicted using the earlier derived combined parameter values for fractional densities less than 98 -%. For fractional densities above 98-%, significantly slower consolidation rates are predicted using the new parameter values, resulting in a smooth transition to intact salt behavior at full consolidation. Based on the results shown in these analyses, the consolidation rates at high fractional densities (densities greater than 98-% of the density of intact salt) are slightly greater using the shear database values than those predicted using the combined database values. Additionally, the consolidation rates predicted using the combined mechanism model are greater than the consolidation rates predicted using the modified Zeuch and Spiers models. The consolidation rate of the combined mechanism model can either be greater than or less than that predicted by the modified Sjaardema-Krieg model, depending on the fractional density. The modified Sjaardema-Krieg model predicts a nearly linear consolidation rate for all fractional densities; whereas, the consolidation rate predicted by the combined mechanism model is initially greater than that predicted by the modified Sjaardema-Krieg model but is significantly reduced at fractional densities greater than 98-%, which is more representative of observed laboratory data.

7.0 SUMMARY AND CONCLUSIONS

Crushed salt is planned to be a major long-term component of the shaft seal system at the WIPP site. The crushed-salt seal gradually becomes effective over time as consolidation, caused by creep of the surrounding intact salt, produces shaft closure and loading of the crushed salt. The ability to predict creep consolidation of crushed salt has been important to the design and evaluation of WIPP seals and will undoubtedly be useful in the pending recertification required of the WIPP site. The work reported here represents a culmination of several laboratory and analytical studies devoted to constitutive models for crushed-salt reconsolidation. These earlier studies provided the theoretical bases and laboratory data that support the crushed-salt, combined-mechanism constitutive model. The prior studies, discussed in Section 1.2, have been documented in publications and reports and are summarized by Hansen et al. [1998].

In this study, additional laboratory tests were added to the crushed-salt database. Two new laboratory shear consolidation experiments were conducted with fractional densities near the initial fractional density expected in the dynamically compacted crushed-salt seal (approximately 0.9). These tests expand the database in the fractional density ranges expected in situ and provide information on the crushed-salt flow behavior as its density increases. The expanded database was fit to obtain material parameter values for the crushed-salt constitutive model. The results of the model fitting produced material parameter values representative of the entire database. Two separate fits were performed. The first fit used only the shear consolidation tests in the database, and the second fit used both the shear and hydrostatic consolidation tests. In our previous studies before development of the combined-mechanism model, dramatic changes in the parameter values were observed when the different tests were fit. In the present study, these separate fits produced similar parameter values, which indicates that the constitutive model is more representative of the physics of creep consolidation of crushed salt than were the previous models. These parameter values were used to validate the model against tests outside of the database with different load paths. Three constant strain-rate tests were predicted with the crushed-salt model and compared to the laboratory data. The predicted strains were found to compare quite well with laboratory results; whereas, the predicted axial stress was generally greater than the laboratory measured stresses. Application of the model was demonstrated for typical shaft sealing analysis problems, which illustrate the expected change in fractional density with time for different depths of the shaft seals.

As a result of this study, a constitutive model for crushed salt is available that contains the observed mechanisms for crushed-salt consolidation. When consolidation is complete, the model

predicts intact salt behavior. The model characterizes the experimental data quite well over a wide range of porosities and stress triaxialities and performs reasonably well for stress conditions and load paths outside of the database used for its development.

APPENDIX A

INPUT FILES TO BMDP, NONLINEAR REGRESSION PROGRAMS 3R AND AR

A.1 DESCRIPTION

The input files required to execute BMDP Program AR and 3R analyses are included in this appendix; specifically, three input files are included. The first file (FLOW.INP) is the input file to the BMDP Program 3R, which was used to determine the flow rate parameters. The second and third files (SHEAR.INP and COMB.INP) are the input files to BMDP Program AR. The input files were used to determine two sets of creep consolidation parameters fit to the shear consolidation database (SHEAR.INP) and the combined shear and hydrostatic consolidation database (COMB.INP).

Basically, the input files can be thought of as a series of paragraphs which are further subdivided into sentences using keywords. Each paragraph is activated by a backslash (/) followed immediately by a keyword. Each of these sentences is activated by keywords and ended with periods. All comment cards are noted using the pound symbol (#). These input files are composed of 12 paragraphs. The first paragraph (/INPUT) contains the title card, the database file name, the format to be used in reading the data, and the number of variables in the database. The second paragraph (/VARIABLES) names each of the 18 variables contained in the database file. The third paragraph (/TRANS) identifies the defined variables (or functions of variables) that are specific to the response model. Specifically, MS and DS are the mean stress and stress difference, respectively. Similarly, D0 and DI are the emplaced and initial fractional density, respectively. The variable USE identifies which test database is to be used in the fit, and the variable WT is the weight function. The fourth paragraph (/REGRESS) identifies the dependent variable (DEPEND), the number of parameters in the model, which variable is the weight function (WEIGHT), which variable number is the integration variable (ITIME) in the rate equations, the number of differential equations (NEQN), the number of iterations (ITER), the number of interval halvings for each iteration (HALVINGS), and the maximum number of integration steps (MAXC). The fifth paragraph (/PARAMETER) identifies the parameter names and the initial estimates, as well as the maximum and minimum values for each of the parameters. The sixth paragraph (/DIFIN) identifies the initial values for each of the dependent variables in the rate equations (Z(i),i=1,NEQN). The seventh paragraph (/DIFEQ) specifies the functional form of the rate equations (DZ(i), i=1,NEQN). The eighth paragraph (/FUN) identifies the dependent variable (response) function (F). The ninth through eleventh paragraphs (/SAVE, /PRINT, and /PLOT) specify output options for the program. The last paragraph (/END) identifies the end of the input file.

#
#     Fit to hydrostatic and shear consolidation tests (icase = 1 & 2)
#
# ================================================================
#
#     This code uses the BMDP routine AR to fit the differential
#     equations that describe the axial and lateral strain in the
#     both the hydrostatic consolidation tests and the
#     shear consolidation tests to determine the parameter values
#     for the crushed-salt, combined-mechanism constitutive model.
#     The parameter values for the flow potential are determined
#     first and then fixed during the fitting in this routine.
#     The parameter values for the M-D consitutitve model are fixed
#     at the values for clean intact salt.  Ten parameter values
#     remain to be determined that describe the effective stress
#     measure (ETA0, ETA1, NF) with ETA2 fixed=1, the moisture and
#     grain size parameters (AA1, PP), and the pressure solutioning
#     parameter values (R1, R3, R4, QSR, NSP).   The independent
#     parameters are:
#        1.  mean stress                              (MS)
#        2.  stress difference                        (DS)
#        3.  emplaced fractional density              (D0)
#        4.  initial fractional density               (DI)
#        5.  grain size                               (DC)
#        6.  absolute temperature                     (T)
#        7.  moisture content                         (W)

APPENDIX B

LATERAL-TO-AXIAL STRAIN-RATE RATIO MODEL FITS TO THE SHEAR CONSOLIDATION TESTS

This appendix contains the plots of the model fits to the 18 shear consolidation tests used to determine the flow potential parameters. Each plot shows the measured and predicted lateral-to-axial strain-rate ratios as a function of density for each of the 18 tests. Test conditions included on the figures correspond to the target test conditions given in Table 3-2.

APPENDIX C

CRUSHED-SALT CONSTITUTIVE MODEL FITS TO THE HYDROSTATIC AND SHEAR CONSOLIDATION TESTS

This appendix contains plots of the crushed-salt, combined-mechanism constitutive model fits to the 40 hydrostatic consolidation tests and the 18 shear consolidation tests. Two plots are included for each test depicting the fits to two test databases; namely, (1) a database containing the 18 shear consolidation tests only and (2) a database containing the combined 58 shear and hydrostatic consolidation tests.

The appendix contains 58 figures. Each figure shows the two model fits to each particular laboratory test; either a hydrostatic consolidation test (Figures C-1 through C-40) or a shear consolidation test (Figures C-41 through C-58). The plots labeled *Shear Database* represent the crushed-salt constitutive model fit to the shear test database, and the plots labeled *Combined Database* represent the crushed-salt constitutive model fit to the combined test database. As discussed in Section 4.6.4, shear database curve fits do not appear for Figures C-27 and C-28 because the tests are outside the range of the shear database parameter values.

ACKNOWLEDGEMENTS

Many individuals assisted in field work, data reduction, and editing. We want to extend special thanks to John Morse who recognized the importance of small brine inflows into the WIPP facility excavations, and with the assistance of Bruce Hassinger, formulated the plans that lead to the present study. Mel Balderrama designed and installed early versions of the brine collection devices and made many valuable observations and suggestions. Tom Dillon and Dave Belski provided both encouragement and technical advice in the early stages of the study. Pitor Skiba, Rick Deshler, Mel Balderrama, and Dave Belski were responsible for most of the underground data collection. Review comments by Wes Patrick, Joe Register, Roy McKinney, and Bob Kehrman were especially valuable.

BRINE SAMPLING AND EVALUATION PROGRAM PHASE I REPORT

DOE-WIPP-87-008

EXECUTIVE SUMMARY

This report presents preliminary data obtained in the course of the WIPP Brine Sampling and Evaluation Program. The investigations focus on the brine present in the near-field environment around the WIPP underground workings that flows under existing pressure gradients. Most of the data reported in this document were acquired in the 600 days after January 1, 1985.

Although the WIPP underground workings are considered "dry," small amounts of brine are present, probably on the order of 0.1 to 0.5 percent by weight of the surrounding rocks. This amount of brine is not unexpected in rocks of marine sedimentary origin. Part of that brine can and does migrate into the repository in response to pressure gradients, at essentially isothermal conditions. These small volumes of brine have little effect on the day-to-day operations, but are pervasive throughout the repository. Enough moisture may accumulate over a period of years to affect both operations and planning during the life of the project and the behavior of repository during resaturation and repressurization after sealing and closure.

The preliminary observations made during Phase I of the Brine Sampling and Evaluation Program (BSEP) began informally as an extension of the weep observations in 1983, and included observations made during 1984 of localized weeps and the growth of tubular salt stalactites at various locations in the WIPP underground. Brine occurrences manifested by salt efflorescences, moist areas, and fluid accumulations were also commonly observed in association with drill holes and at some locations on the floors of the workings. The studies were organized in 1984 and formalized in 1985. Moist areas and locations of brine inflows have been observed in all parts of the WIPP underground. The list of 70 drill holes included in Appendix B is not all-inclusive, but illustrates the widespread distribution of the occurrences.

Very small volumes of brine have been observed to "weep" from newly excavated surfaces in the WIPP underground workings. They appear as irregular moisture patches on the ribs and back. Some become visible immediately after excavation, while others may take up to several weeks to become noticeable. As the brine evaporates into the repository atmosphere, halite and very minor amounts of other evaporite minerals are precipitated, usually in the form of finely crystalline encrustations, mounds, and knobs. Individual accumulations are generally less than two centimeters in diameter, but sometimes coalesce to form small masses or ridges. Weeps are pervasive throughout the underground workings and occur on the surfaces of all exposed lithologic units. They appear to develop more quickly and occur more frequently on the units that contain some clay.

Small quantities of gas are associated with some weeps. Slowly bubbling wet areas, usually about 2 or 3 centimeters in diameter, are occasionally very noticeable within a few minutes of mining. The bubbling usually decreases

within an hour or two after mining, and the rate of inflow to freshly mined surfaces of both brine and gas decreases rapidly. Most of the moisture appears slowly over periods of hours or days, and associated gas inflows are so small as to go unnoticed and be difficult to detect. Some of the weeps remain visibly moist for fairly long periods of time, but most appear dry after several months. Manually probing the halite encrustations often reveals that many of the "dry" encrustations are damp within, indicating that the inflow of brine has only decreased in flow rate, not ceased entirely.

More than 1400 holes aggregating over 14 kilometers in total length have been drilled from the WIPP underground excavations. Mostly vertical and horizontal holes, most are 15 meters or less in length. The majority are 15 centimeters (six inches) or less in diameter, although holes almost a meter (36 inches) in diameter and 6 meters long have been drilled. A preliminary listing of those holes drilled before July 1985 is included as Appendix A of this report. Fifty-four of these holes were used as observation locations during Phase I of the BSEP and are listed in Appendix B of this report.

Encrustations of halite on the sides and at the collars of the holes indicate that small volumes of brine have seeped into nearly all of them. Measurable volumes of brine have accumulated in some holes.

In the fall of 1984, at the time the BSEP was initiated, it was realized that many of the more noticeable brine occurrences were found in drill holes that had been in existence for some time and that little or nothing was known about the rate of initial brine inflow. Seventeen new holes that were drilled as part of already-planned stratigraphic data collection became available for brine observations.

Some of the then-existing brine occurrences were scheduled to be disrupted by planned experiments, especially in Room J and Experimental Rooms A1, A2, A3, and B. As a result, initial emphasis was to obtain expeditiously some baseline data prior to such disruptions, with the realization that the BSEP would evolve as the nature of the brine inflows became more apparent.

Measured occurrences have inflow rates that range from less than the rate at which surface moisture is evaporated into the repository atmosphere to approximately 0.5 liters per day. Individual occurrences vary greatly and some drill holes separated by less than a meter have inflows that contrast dramatically, making the discussion of "averages" or "typical occurrences" difficult or misleading. The reasons for this variability are still poorly understood. The inflow at any specific location is influenced by a number of factors, including local stress distribution, local brine sources, variations in local fracturing and permeability, and local variability in the geology. Most occurrences displayed a brief, initial no-flow or low-flow period, followed by maximum inflow. Brine inflow then decreased over a period of several months to relatively steady-state conditions over the 600 days of monitoring. Some occurrences had increased inflows and some ceased entirely. Most of the measurable inflow rates range between a few tenths and a few hundredths of a liter per day. The largest individual production measured during this reporting period produced an aggregate over 235 liters of brine, and continues

to produce approximately 0.2 liters per day. It was clearly an unusual and exceptional occurrence and was associated with excavation-induced fracturing. Inflow rates into that drill hole have declined markedly over the observation period.

It should be noted that the brine occurrences discussed here are small and are clearly distinguished from the "brine reservoirs" found in the underlying, stratigraphically lower, and geologically older, Castile Formation in the Delaware Basin. "Brine reservoirs" are measured in hundreds of thousands of liters, flow readily into boreholes that penetrate them, and have been the subject of other investigations.

The BSEP is focused on the brine, not the gas, occurrences noted at WIPP. One important observation made during Phase 1 of the BSEP is that gas flow and brine flow appear to be intimately related. Gas is associated with many weep occurrences on freshly-mined faces. Gas commonly exsolves from solution as the brine is poured from one container to another. Gas is observed bubbling up through many of the brine occurrences. Fractures, commonly measured in fractions of a millimeter in width and a few meters in length, contain gas and brine in sufficient volume and under sufficient pressure to keep the fractures at least slightly open under lithostatic pressure.

The observations document that salt creep closure and two-phase fluid flow are occurring simultaneously, at least in the immediate vicinity of the repository excavations. It is still not clear what effect the coupling of these processes have on brine inflow or repository behavior. The resaturation of the openings which include the spaces within the waste storage areas (between and within waste containers and between any backfill), the access drifts, and the fractures in the salt, are presently being considered in light of the coupling of these processes. Data collected as part of the BSEP will continue to feed those modeling efforts.

It is clear from the preliminary data that significant pressure-driven brine inflows that are not the result of brine migration in a thermal gradient may occur after sealing and closure of the repository. Brine flow systems are not well understood at this time, but it is likely that the observed inflows are dominated by the response to transient pressure gradients resulting from the excavation of the repository. A component due to regional hydraulic head cannot be ruled out at this time, but if it exists, appears to be relatively small.

Brine chemistry data have been collected, but are not reported in this document. Characterization of the near-field brine chemistry continues, and will be included in a future BSEP report.

The major observations may be summarized as:

- Brine inflows are small, and are not related to large brine reservoirs in the Castile Formation.

- Brine occurrences, particularly those evidenced as halite efflorescence, are pervasive throughout the WIPP underground workings.

- Brine inflow rates are low, usually on the order of a few hundredths of a liter per day or less.

- Although small when measured in terms of liters per day at any given location, cumulative inflow volumes may be significant when measured in terms of the entire repository over periods of many years.

- There is a considerable variation in brine inflow between locations, even when locations are only a few meters (or, in some instances, less than a meter) apart.

- Holes that penetrate the roof and floor generally show a pattern of an initial, maximum flow rate that reduces to a fairly steady flow rate over the time period during which measurements have been made.

- Several flow systems and conditions are possible, but insufficient data exist to select the system and conditions (or combination of several systems and conditions) that best describe the phenomena at WIPP.

BRINE SAMPLING AND EVALUATION PROGRAM PHASE I REPORT

DOE-WIPP-87-008

ABSTRACT

This interim report presents preliminary data obtained in the course of the WIPP Brine Sampling and Evaluation Program. The investigations focus on the brine present in the near-field environment around the WIPP underground workings that is easily moved under existing pressure gradients. Observations began in 1983 and were expanded in 1984 and 1985. Most of the data reported in this document were acquired in the 600 days after January 1, 1985.

Although the WIPP underground workings are considered "dry," small amounts of brine are present, probably on the order of 0.1 to 0.5 percent by weight of the surrounding rocks. This amount of brine is not unexpected in rocks of marine sedimentary origin. Part of that brine can and does migrate into the repository in response to pressure gradients, at essentially isothermal conditions. These small volumes of brine have little effect on the day-to-day operations, but are pervasive throughout the repository and may contribute enough moisture over a period of years to affect resaturation and repressurization after sealing and closure.

The inflows occur as "weeps" on the exposed surfaces and as very small inflows of brine at various locations, most noticeably in holes drilled outward from the underground workings. Over 1400 underground drill holes, most 15 meters or less in length, exist at WIPP. Gas is usually associated with the brine inflows. Gas bubbles are observed in many of the brine occurrences. Gas is also known to exsolve from solution as the brine is poured from container to container.

Measured brine occurrences have inflow rates that range from less than surface evaporation rates to approximately 0.5 liters per day. Most range between a few tenths and a few hundredths of a liter per day. Individual occurrences vary greatly and some drill holes less than a meter apart have brine inflows that contrast dramatically, making the discussion of "averages" or "typical occurrences" difficult or misleading. Most occurrences have initial peak inflow rates that decline to steady rates over the observation period. Some have ceased entirely, and a few have increased inflows.

The largest individual production that was measured during this reporting period produced an aggregate of over 235 liters of brine. It was clearly an unusual and exceptional occurrence, and inflow rates for that occurrence have declined over the observation period.

It is clear from these preliminary data that the brine, gas, and salt creep phenomena are intimately associated. Pressure-driven brine inflows that are not the result of brine migration in a thermal gradient may occur at any time a pressure difference exists, including after sealing and closure of the repository. It is likely that the observed inflows into the repository excavations are dominated by the response to transient-pressure gradients

resulting from the excavation of the repository itself. A component due to regional hydraulic head cannot be ruled out at this time, but if it exists, it appears to be relatively very small.

Investigations of the occurrence and chemistry of the brines are continuing.

1.0 INTRODUCTION

The Waste Isolation Pilot Plant (WIPP) is a Department of Energy (DOE) research and development facility to demonstrate the safe disposal of radioactive wastes derived from the defense activities of the United States. The WIPP project's mission consists of two parts. The first is to demonstrate the safe handling and disposal of transuranic (TRU) waste in bedded salt. The second is to create a research facility for the examination of the technical issues related to the emplacement of defense-related radioactive waste in bedded salt.

The WIPP facility is located approximately 42 kilometers east of Carlsbad, New Mexico, in an area known as Los Medanos (Figure 1-1). The underground portion of the facility is located at a depth of approximately 655 meters in the bedded salt deposits of the Salado Formation, part of an evaporite sequence over 1000 meters thick (Figure 1-2). An extensive program of site characterization and validation has been conducted for the past ten years (1976-1986). The results of these studies are summarized in the WIPP "Geological Site Characterization Report" (Powers et al., 1978), the WIPP "Safety Analysis Report" (US DOE, 1986), the WIPP "Preliminary Design Validation Report" (Bechtel National, Inc., 1983), and the WIPP "Results of Site Validation Experiments" (Black et al., 1983). Additional site investigations are being conducted as part of an ongoing program to further refine the understanding of the site-specific geology. The hydrogeological activities of the Brine Sampling and Evaluation Program, as outlined in the Brine Testing Program Plan (Morse and Hassinger, 1985), are part of these investigations.

The purpose of the Brine Sampling and Evaluation Program (BSEP) is to investigate the origin, hydraulic characteristics, extent, and composition of brine occurrences in the excavations for the WIPP repository in the Salado Formation. Although considered dry workings, brine is observed to weep from exposed surfaces in the repository horizon and seep into drill holes in the underground excavations.

These brine occurrences become visible shortly after excavation or drilling. The more noticeable occurrences produce brine at the rate of a few tenths or a few hundredths of a liter per day or less. In locations where evaporation is very slow, a total of a few liters to several hundred liters of brine have been observed to accumulate over a period of weeks or months.

Although individual occurrences are small and not particularly noticeable on a day-to-day basis, they are pervasive throughout the repository. Over a period of months and years they may contribute enough moisture to merit consideration from the standpoint of long-term repository performance. During present operations, virtually all of the moisture entering the workings from the host rock is evaporated and removed in the air circulated by the underground ventilation system. The assessment and understanding of the brine occurrences becomes especially important when considering what their long-term impacts might be on operations during the demonstration and retrieval period and the rates of resaturation and repressurization of the excavations after closure of the facility.

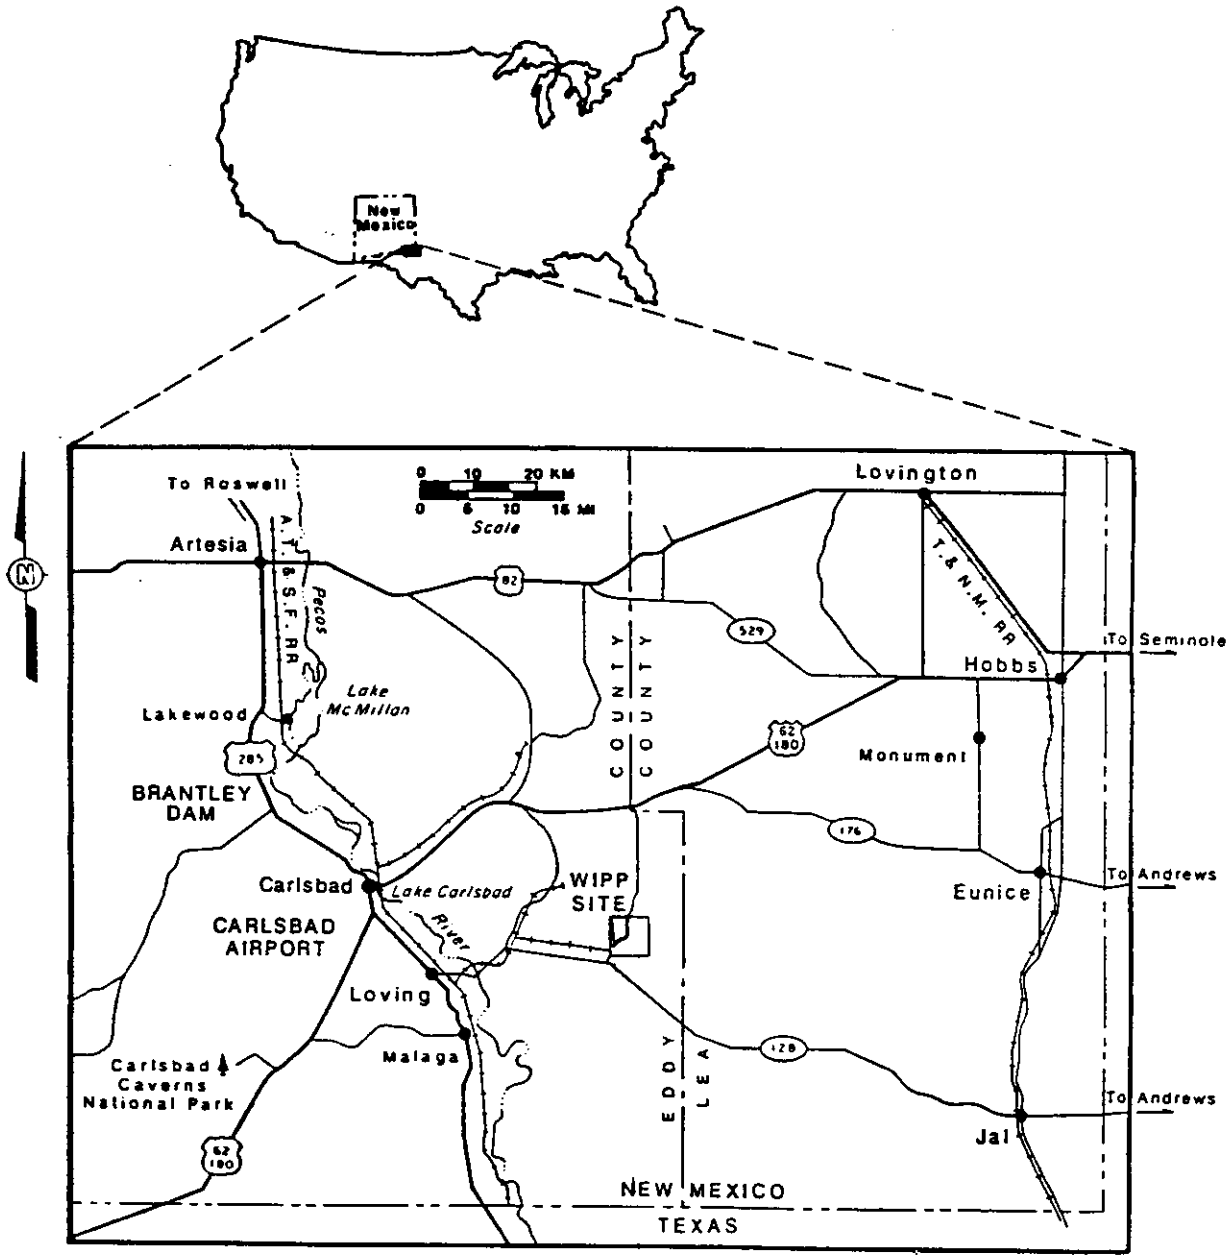

Figure 1-1.
Location Map of the WIPP Site

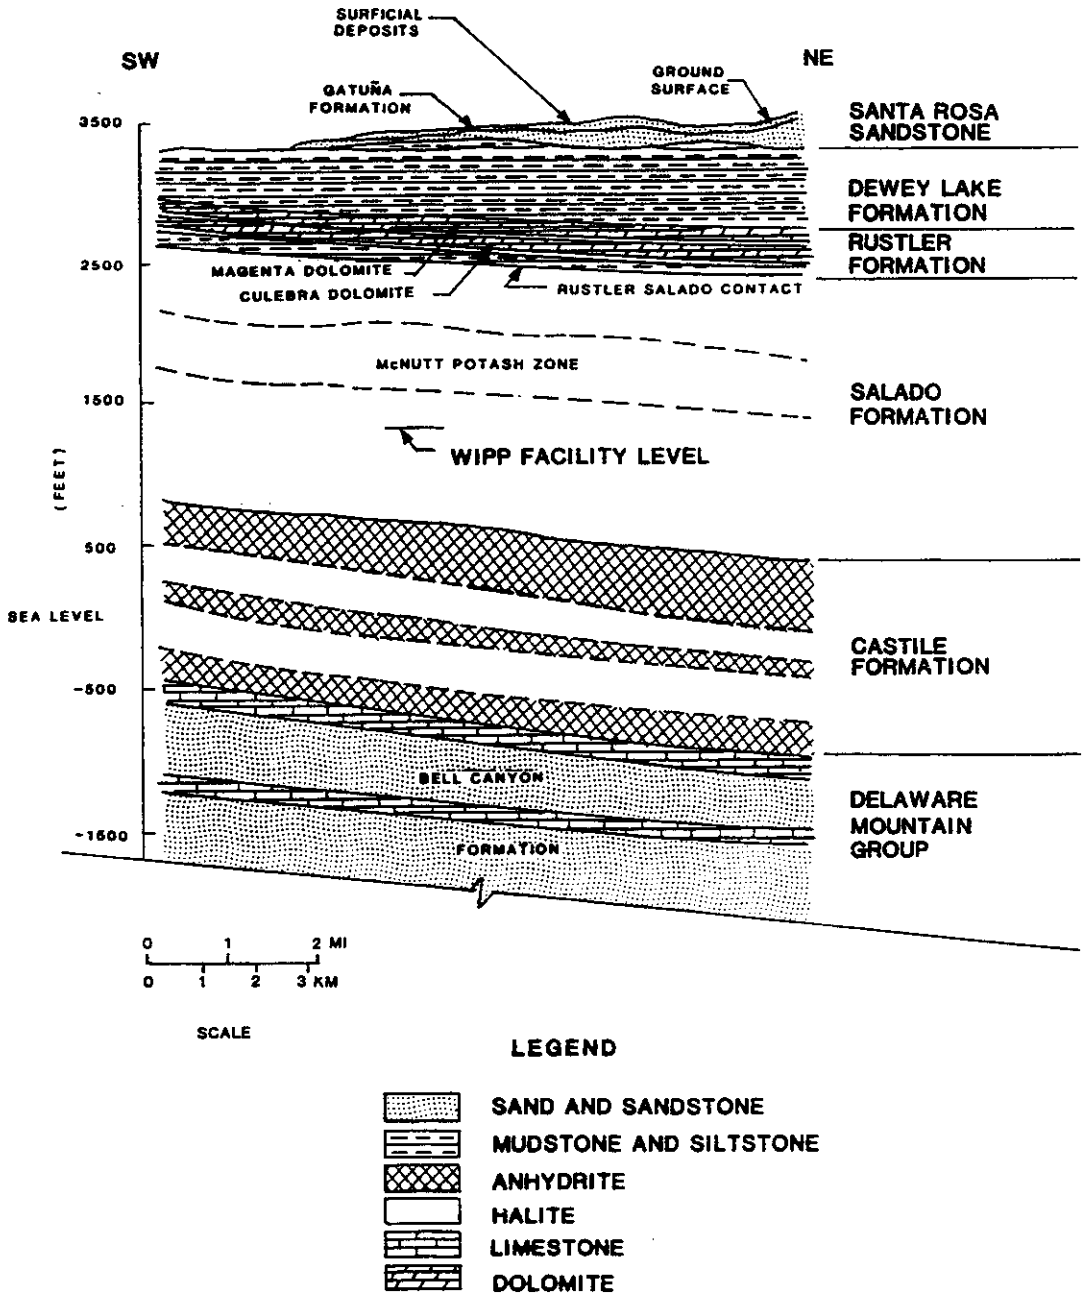

Figure 1-2.

Generalized Stratigraphic Cross Section

1.1 OBJECTIVES OF THE BRINE SAMPLING AND EVALUATION PROGRAM

The objectives of the BSEP are to characterize the hydraulics, extent, and composition of the brine occurrences in the excavations for the WIPP repository. The emphasis of this program is on those aspects of the brine occurrences that are likely to affect operations, resaturation and repressurization, and overall facility performance. The following topics are being investigated and an assessment of their relative importance is being made:

- Brine sources
- Paths for brine movement
- Mechanisms of brine movement
- Aerial extent and volume of existing and potential sources of brine
- Relationship between brine and gas occurrences
- Long-term behavior of known brine occurrences (self-limiting, persistent, etc.)
- Inflow to be anticipated during the demonstration and retrievability period
- Inflow to be anticipated after closure
- Brine composition as it might relate to the above concerns, with emphasis on the anticipated aggregate composition of brines that might enter the repository after closure.

1.2 PHASED APPROACH

This program is being conducted in three phases. Phase I was initiated in the Fall of 1984, and continued throughout 1985 and into 1986. This phase was designed to initiate the program, make preliminary observations, and to provide sufficient data on the characteristics and distribution of the brine near the repository so that a detailed and coordinated investigation could be carried out in Phase II. This document is an interim status report for Phase I.

Phase II continues selected Phase I investigations. It includes additional instrumentation and testing to further refine the understanding of brine occurrences and their chemistry and hydrology, and to identify long-term testing needs and techniques. Phase II was initiated in early 1986 and will continue into early 1987. A Phase II interim report will be issued in 1987.

Phase III monitoring will continue throughout 1987, and is intended to lead directly into a long-term monitoring program expected to continue for the operational life of the facility. A Brine Sampling and Evaluation Program final report will be issued in 1988.

The long-term brine monitoring program, which will continue throughout the life of the facility, will be coordinated with other WIPP monitoring programs.

1.3 PHASE I TASKS

Phase I of the Brine Sampling and Evaluation Program includes five specific tasks that are outlined in Appendix A of the "Brine Testing Program Plan" (Morse and Hassinger, 1985). This report covers Task 1 and Task 2 activities.

- Task 1 included the development of an inventory of drill holes in the WIPP underground with the objective of identifying those open holes that might be locations where preliminary observations could be made for the BSEP. Task 1 also included the review of literature concerning similar low-flow and weeping brine occurrences both at WIPP and other mines. Task 1 activities are described in more detail in Section 1.3.1.

- Task 2 involved the collection of preliminary data from existing, accessible brine occurrences within the underground workings at WIPP. Encountering these occurrences provided insight into the complex nature of the brine inflows. Some test installations were made specifically for the purpose of brine inflow observations as part of Task 2. Task 2 activities are described in more detail in Section 1.3.2.

- Task 3 was the development of a sampling and testing plan for Phase II of the BSEP. Task 3 included the testing of techniques, the refinement of the criteria for the identification of brine sampling locations, and the refinement of sampling procedures and rationale.

- Task 4 focuses on the assessment of the feasibility of using geophysical techniques to define source horizons and the aerial extent of brine occurrences at the repository level. This task is continuing.

- Task 5 was to be the coordination of Phase I tasks with the Gas Testing Program (GTP) (Torres, 1985). However, the GTP was delayed and no coordination was necessary.

1.3.1 TASK 1 ACTIVITIES

The Brine Testing Program Plan (Morse and Hassinger, 1985) stated that this task would consist of the following activities:

- Review literature pertaining to similar low-flow and weeping conditions in other mines to develop an understanding of brine occurrences.

- Review and evaluate previous WIPP brine characterization and gas testing methodology, data, and reports, in view of their applicability to this program.

- Assemble a master inventory and map of underground boreholes from current lists available from Sandia National Laboratories (SNL), Bechtel, Westinghouse, and the mining contractor.

- Verify locations and determine the status, condition, and accessibility of these holes.

- Develop a separate inventory of accessible boreholes in which a determination of the presence or absence of brine can be made, and monitor all of these holes periodically through the duration of the program.

- Develop criteria for identifying boreholes suitable as test sites for the BSEP.

- Identify boreholes suitable as future test sites for the BSEP.

- Evaluate the applicability of available equipment on hand for pressure-transient testing in boreholes.

1.3.2 TASK 2 ACTIVITIES

The goal of Task 2 was to acquire preliminary data for the BSEP, concentrating on the sampling and evaluation of known, easily accessible brine occurrences in the WIPP underground workings. The overall objective was to obtain an initial understanding of the rate at which brine flows into open drill holes and to make a preliminary assessment of the volume of brine likely to be involved in an individual occurrence.

In order to attain this goal, Task 2 is comprised of the following activities (Morse and Hassinger, 1985):

- Removal of brine from accessible boreholes in the floor, using compressed air or other evacuation techniques such as bailing.

- Monitor additional boreholes to be drilled for the Materials Interface Interaction Test (MIIT) and Drum Durability Test (DDT) programs in Room J.

- Initiate brine sampling for preliminary chemical analysis for major and minor ions to identify analyses that will provide useful results. (Sampling for brine chemistry is continuing. The results will be included in a later report.)

- Drill boreholes in an appropriate grid pattern around selected known occurrences. Use isolation techniques and varying depth holes to determine the stratigraphic zones contributing to brine inflow.

- Drill horizontal boreholes in selected areas along ribs to assess spatial distribution of weeps.

- Attempt pressure transient testing in holes with existing equipment, if appropriate.

2.0 INVENTORY OF UNDERGROUND DRILL HOLES

2.1 Objectives

One part of the Task 1 activities was to assemble a master inventory of underground boreholes from lists available from SNL, Bechtel, Westinghouse, and the mining contractor. Most of the holes that were drilled in the WIPP underground were intended to have instrumentation installed in them. The primary objective of compiling the inventory of underground drill holes was to assist in locating those few holes that remain open (not filled with liners, casing, or instrumentation) and to document the suitability of those open holes for use in the BSEP.

2.2 Methodology

Available lists of underground drill holes were obtained and compiled into a computerized inventory, maintained on an IBM XT microcomputer utilizing dBase III software. Twenty-two sources of information were used. Locations, directions, and hole dimensions are either from as-planned or as-built data, or are approximated. Where possible, as-built data was utilized. Selected holes were located underground and visually inspected. Field observations were added to the location data contained in the computerized listing.

2.3 Accomplishments

The borehole inventory compilation resulted in a listing of 1439 holes that are known to have been drilled in the WIPP underground prior to July 1985. Most of these holes are less than 15 meters in length.

That list is attached to this report as Appendix A. It should be noted that this appendix is a preliminary listing that is based in part on unchecked information and should not be used as a definitive reference for the location or existence of underground drill holes. It does, however, serve the intended purpose of the BSEP in identifying almost all of the open holes that are accessible in the WIPP underground that might serve as points for observations of brine, fractures, or other geological occurrences or conditions. Fifty-four of these holes were used as observation locations during Phase I of the BSEP. They are listed in Appendix B.

Most of the drill holes have been made for the purpose of installing some sort of instrumentation. As a result, the vast majority were not accessible for brine inflow observations. Additionally, some holes were known to have been destroyed by subsequent mining activities. A preliminary designation of the status of each hole was made during the compilation of Appendix A. Those designations were:

Abandoned hole or instrument
Collar destroyed by mining
Closed hole
Hole used for experiment
Filled with grout
Lined with inclinometer guide-tube

Instrument in hole
Mined out
Rock bolt in hole

A preliminary underground field check was made of those holes listed with the status of abandoned or containing a failed instrument. Additional observations of other holes were made during routine underground work. If a hole was field checked and known to be open, it was designated as having an open status.

A preliminary listing of those holes known to be open or possibly open, (as indicated either as a status of "abandoned hole or instrument location" or "status unknown," has been abridged from Appendix A. That list contains references to 365 holes and was used as a tool to help locate holes that might be suitable for use as observation or sampling points for Phase I of the BSEP. For such use, a hole had to meet the following criteria. It had to be:

Open
Not used for a conflicting purpose
Accessible for repeated, periodic observations

The suitability of existing holes for use in transient-pressure testing was also a criteria that was initially considered.

As Phase I proceeded, it became apparent that if a hole had been in existence for a long enough period of time and had received sufficient brine inflow to be of interest for transient-pressure testing, significant salt buildups had formed on the sidewalls and, in the case of upholes, at the collar. These salt buildups will interfere with the proper seating of packers and the holes will have to be reamed before there is a chance of success in any transient-pressure testing. It also became obvious that there was enough variation in brine inflow between holes located less than a meter apart, that considerable effort needed to be expended to define probable inflow locations within holes before attempting pressure transient testing. Phase I has concentrated on acquiring accurate information as to the general nature (including stratigraphic controls, if any) of the brine weeps and inflows.

Seventeen new drill holes, sixteen of which were 15 meters (50 feet) deep, were drilled in early 1985 for stratigraphic information. The sixteen 15-meter (50-foot) holes consisted of eight pairs of upholes and downholes which span the northern end of the WIPP underground, a distance of approximately 1300 meters, east to west (Figure 2-1). These holes were available for use in the BSEP and have been monitored for brine inflow since they were drilled.

These seventeen holes, coupled with some observations from several existing holes elsewhere in the workings, provided the data base for Phase I investigations without additional drilling (Appendix B).

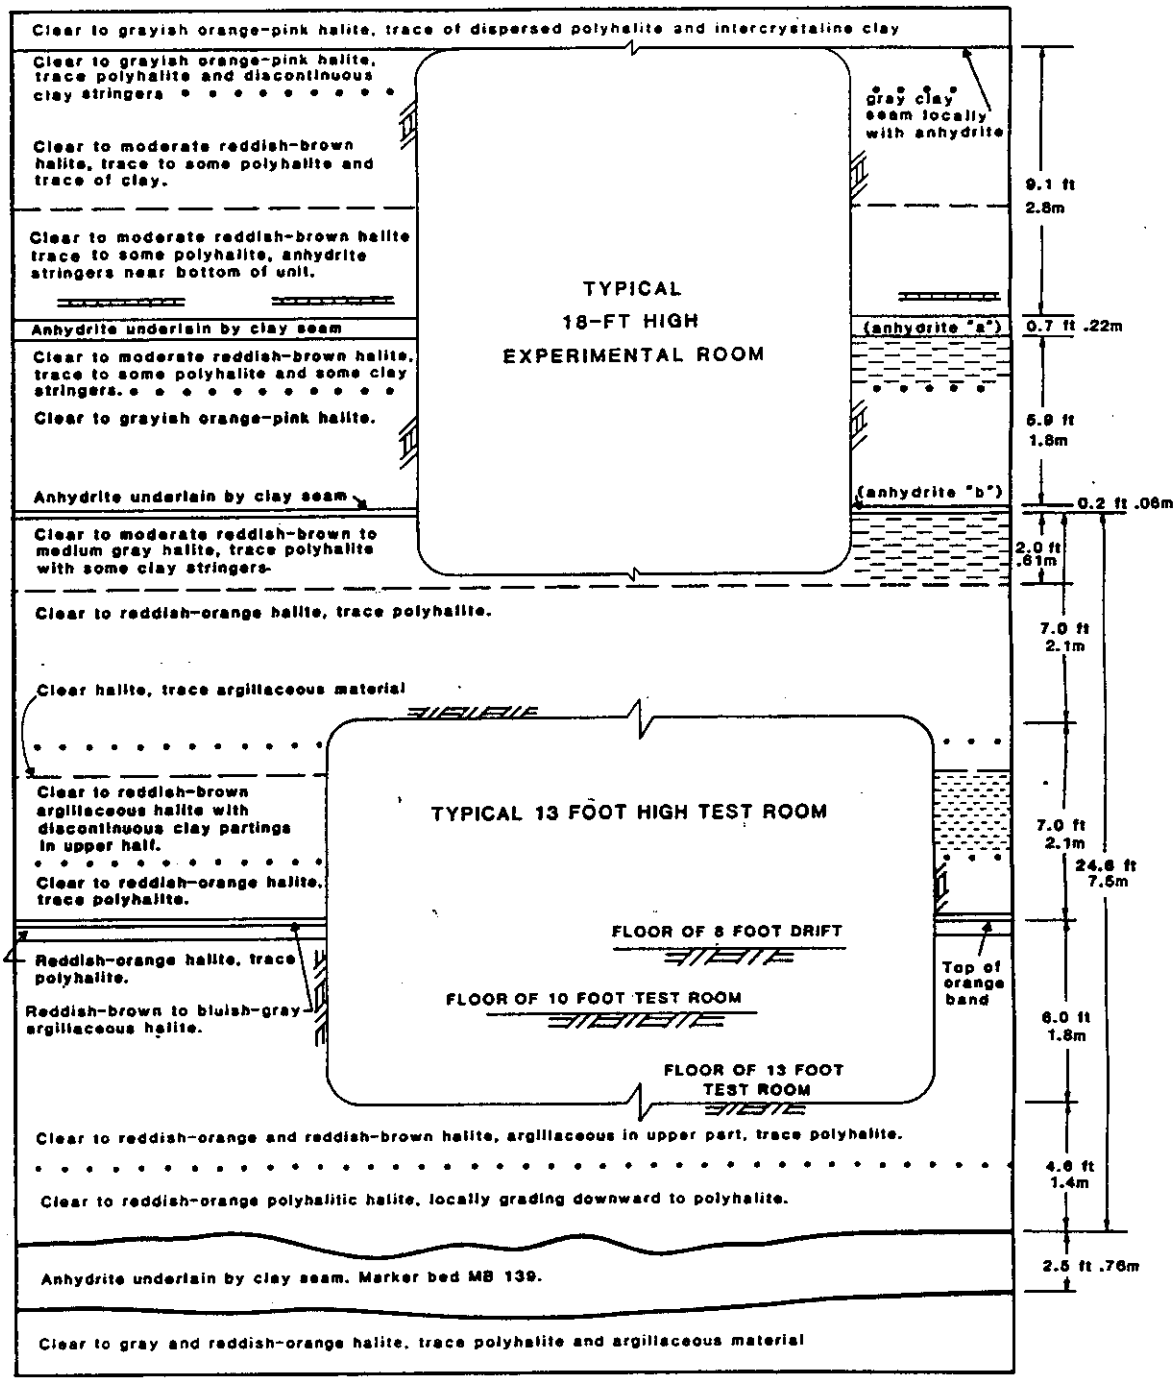
DH37 Inflow Rates

Figure 3-1.
Brine Weeps in the WIPP Facility Excavation



NOTES:

1. Dimensions and lithologic descriptions are derived primarily from corehole and geologic mapping data from the four test rooms and experimental area supplemented by geologic information from the remaining SPDV excavation.
2. Unit thicknesses are approximate and vary slightly.
3. Room dimensions have changed with time due to salt-creep closure.

Figure 3-2.

Geologic Cross Section of the Facility and Experimental Level in the Vicinity of the SPDV Test Rooms and the Experimental Rooms

the weeps remain visibly moist for fairly long periods of time, but most appear dry after several months. Manually probing the halite encrustations often reveals that many of the "dry" encrustations are damp within, indicating that the inflow of brine has only decreased in volume, not ceased entirely.

Several factors are hypothesized to cause the decreased inflow rates observed to occur in the weeps noticed shortly after mining. As the transient effects of mining (discussed in more detail in Section 4.2) affect a zone ever farther from the excavated openings, local pressure gradients within a half-meter or so of the excavations probably lessen and the driving mechanism for brine and gas inflow decreases. With time, the moisture in the salt in immediate proximity to the underground openings has been driven to the surface, requiring that additional brine migrate over longer distances for inflow to continue. As evaporation into the repository atmosphere continues, more and more crystal growth takes place. This may well result in partial sealing of the surface by new halite crystals and probably results in a reduction of the permeability at the rock-air interface. Converseley, this sealing affect may be offset by an increased porosity, permeability, and fracturing in the "disturbed zone" close to the excavation, as discussed in Section 4.2.1.1. The cumulative effect of the transient conditions and the changes that take place in the physical and hydrological properties of the salt close to the mine openings is not completely understood at this time.

3.1.2 BRINE IN DRILL HOLES

More than 1400 holes aggregating over 14 kilometers in total length have been drilled from the WIPP underground excavations. They extend in all directions, and most are 15 meters or less in length. The majority are 15 centimeters (six inches) or less in diameter, although holes almost a meter (36 inches) in diameter and 6 meters long have been drilled. A preliminary listing of those holes drilled before July 1985 is included as Appendix A of this report.

Encrustations of halite on the sides and at the collars of the holes indicate that small amounts of brine have seeped into nearly all of them. Noticeable amounts of brine have accumulated in some holes.

In the fall of 1984, at the time the BSEP was initiated, it was realized that many of the more noticeable brine occurrences were found in drill holes that had been in existence for some time and that little or nothing was known about the rate of initial brine inflow. Seventeen new holes that were drilled as part of already-planned stratigraphic data collection became available for brine observations.

Some of the then-existing brine occurrences were scheduled to be disrupted by planned experiments, especially in Room J and Experimental Rooms A1, A2, A3, and B. As a result, initial emphasis was to obtain expeditiously some baseline data prior to such disruptions, with the realization that the BSEP would evolve as the nature of the brine inflows became more apparent (Morse and Hassinger, 1985).

The locations where Phase I brine observations were made are listed in Appendix B, which also contains the drill-hole data (depth, diameter, etc.). The locations of the drill holes that are described in more detail in the following sections of this report are shown on Figure 2-1, a map of the WIPP underground workings. Details of the results of Phase I preliminary brine sampling and evacuation of the drill holes in the WIPP repository horizon is presented in Appendix D. Appendix E consists of tabulation of the data discussed in Appendix D.

3.1.2.1 Downholes

Fluid has collected in a number of the vertical downholes drilled in the floor of the underground workings. At the time the BSEP was initiated, it was noted that some holes were filled or nearly filled with fluid, with individual accumulations occasionally totaling many liters. Brine from one hole flowed onto the floor of the East 140 drift at South 850 (TSC-D'Appolonia, 1983b, Part II; Morse and Hassinger, 1985). This hole was plugged during the excavations that lowered the floor of the East 140 drift.

During construction and experimentation, some brine and water has been introduced into the facility. At the time the BSEP was initiated, it was not known how much of the brine found in the downholes was a result of natural inflow from the surrounding salt and how much was a result of intentional or inadvertent introduction of water, whether for dust control, from leaking water pipes, inflow from water-bearing units in the Rustler Formation above the salt down the shafts prior to grouting, or from other construction or experiment related activities (Morse and Hassinger, 1985).

Plugs inserted below the collar of many of these holes have created a restricted environment within them, which reduces the amount of moisture lost by evaporation. As a result, the observations made in plugged downholes may be more representative of inflow conditions in general than those made in upholes or horizontal holes.

One objective of Phase I of the BSEP was to obtain some preliminary figures for naturally-occurring flow from the surrounding salt beds by making systematic observations at existing holes. The following is a summary of the more detailed discussion contained in Appendix D and the data tables in Appendix E.

Brine collection and inflow measurements were made as described in Procedure WP-07-410 (WIPP BSEP: Brine Collection and Inflow Measurements). The general procedure was simply to provide for the accumulation of the small brine inflows, to collect those accumulations on a periodic basis (approximately once a week for initial collections), and to measure the volume that had accumulated since the previous sampling. These measurements were then recorded and tabulated as the average fractions of liters per day collected from each location.

A variety of field techniques were used, depending upon the specifics of each occurrence. They can be divided into the following groups:

- Initial volume measurements, experimental pumping techniques, and water-level measurements
- Vacuum-assisted sampling probe for brine removal from downholes
- Hand-operated rotary suction pump
- Continuous, gravity-driven collecting installations
- Pressure-vacuum and vacuum moisture-sampler installations

Sampling of the downholes was done with a variety of bailing devices, most of which relied on check valves to retain collected brine while the bailer was raised to the surface (the floor of the repository workings). After bailing, the deeper downholes were plugged just below the collar with a piece of plastic foam which was covered, in turn, by a metal lid. The plug and lid prevented the inadvertent introduction of foreign solids into the hole and reduced moisture loss by evaporation to the repository atmosphere.

It should be noted that the northeast part of the repository (Figure 2-1), including Rooms A1, A2, A3, and B, is excavated at a different stratigraphic level, seven meters higher than the rest of the repository (Figure 3-2). The effects of the stress redistribution in the disturbed zone around the repository on the porosity and permeability of the rocks is discussed in Section 4. The fact that anhydrite Marker Bed 139 is seven meters farther below the repository excavations in holes A1X01, A2X01, A3X01, and BX01 than it is in the other downholes monitored for the BSEP, means that brine inflows from this horizon may be occurring through different stress-relieved zones.

A summary of the preliminary data for the downholes sampled during Phase 1 of the BSEP is given in Table 3-1.

General observations are:

- Immediately after drilling of a new hole, there is a short period of time (typically a few days) during which only small brine inflows are observed. This might be the result of damage done to the formation by the drilling itself.
- After the initial no-flow or low-flow period, brine inflows quickly reached maximum inflow rates and began to decline.
- Inflow rates then decreased over a period of several months to relatively steady-state conditions.
- The amount of brine that flowed into drill holes in close proximity to each other varied drastically.

Data summarized and rounded from Appendices D and E.

* I = Increasing
S = Steady
D = Decreasing

Table 3-1.

The data for Hole DH42A in Room G departs from the above observations in several ways. Perhaps most significantly, after the initial brief period of little or no inflow, inflow rates, although high, were not at a maximum, Inflow gradually increased for about three months before reaching a maximum rate. The decline in inflow also took place more slowly and over a longer period of time when compared to the other downholes. The inflow behavior noted at this location is especially interesting when contrasted to that exhibited in Hole DH42 (Figures D-20 and D-21), located two meters to the east and drilled 3.3 meters deeper, which produced approximately one-fourth as much brine.

One of the most important observations is the extreme variation in inflow that was observed between closely spaced locations. In addition to the contrast seen between DH42 and DH42A discussed above, the variations documented in Room 2, Room J, Room L1, and elsewhere are even more striking.

The holes in Room J drilled for the Materials Interface Interactions Test (MIIT) have been described by Morse and Hassinger (1985) and in Appendix D of this report. Over 40 closely spaced shallow drill holes were made and subsequent brine levels within them varied dramatically. Holes partially or completely filled with brine were interspersed with dry or nearly dry holes, often less than a meter away. Deeper drillhole arrays in Room L1 exhibited similar, though less extreme, variations in inflow. The great variation in inflow characteristics between locations only a short distance (a few meters, or in some instances, less than a meter) apart make the discussion of "averages" or "typical occurrences" difficult or misleading. These variations might be explained in part by the effects of mining-induced stress redistributions on porosity and permeability, which are discussed in Section 4.2.

The largest brine production that was observed occurred in Hole NG252 in Room 2, which is discussed at length in Appendix D. NG252 is located close to the west rib (wall) of Room 2 and is 38 millimeters in diameter and 2 meters deep. It is one of the physically smallest of the holes observed and appears to be something of an anomaly. The hole penetrates through anhydrite MB 139, and the brine and gas flowing into this hole appears to enter from a fracture close to the base of MB 139. A dry hole exists, approximately 4.7 meters east of NG252 and on the centerline of Room 2, that is 15 centimeters in diameter, and penetrates into the top of MB 139.

3.1.2.2 Upholes

If the brine inflow into upholes is sufficient to flow down the sides of the hole, moist areas may form on the back (roof). Highly visible salt crust buildups and salt stalactites can also form at the collar of the hole.

Many of the upholes are now inaccessible, usually because they contain installed instruments, and it is not possible to determine the extent of salt buildup within them. If there is enough brine entering the upholes to run down the sides, it will usually flow around the instruments and be evident at the collar. The inflow, coupled with the normally high evaporation rate into the repository atmosphere may cause some stalactites to grow 15 to 30 centimeters per week, but the longer ones are usually quite fragile and break

easily under their own weight or in response to vibrations from the underground equipment. As a result, long stalactites are fairly rare except in undisturbed locations (Figure 3-3). Moisture entering open upholes tends to evaporate readily, as the air can circulate more freely within them. Several techniques were used to seal the collars of the upholes, but none of the techniques completely controlled evaporation (Appendix D). As a result, it is reasonable to assume that the open, accessible holes show heavier internal salt buildup and less buildup and dripping from the collar than equivalent holes which contain instruments or for some other reason have a restricted opening. The data from the upholes should be considered as providing only minimum inflow data.

The data from the upholes is summarized in Table 3-2. As discussed in more detail in Appendix D, the generally much lower and more irregular inflow values for the upholes may reflect the fact that brine was lost by dispersion from the hole collar and evaporation into the repository atmosphere. It is uncertain at this time, however, if all the differences in inflow between the upholes and the downholes can be explained by this mechanism. Further modifications have been made to the collecting techniques used for upholes in order to resolve this question.

The upholes intersect different stratigraphic horizons than those intersected by the downholes. In addition, holes A1X02, A2X02, A3X02, and BX02 are drilled in the back (roof) of rooms at a stratigraphic level approximately 9 meters higher than in the rest of the repository workings. Hole A1X02 is 18 meters long. As a result, the last 3 meters penetrate beds that are not encountered in the other three upholes in Rooms A2, A3, and B. This includes an anhydrite interbed about 2 meters from the end of the hole.

Inflow data from Hole DH215, located at the intersection of E140 and S1950 drifts almost certainly reflect changes in the stress distribution in the disturbed zone in the immediate vicinity of the repository excavations. The effects of mining-induced stress redistribution on porosity and permeability are discussed in more detail in Section 4.2. Inflow increased approximately three hundred percent when additional excavation took place at that intersection and then declined to very small amounts (Section 9.0, Appendix D).

3.1.2.3 Horizontal Holes

Horizontal holes tend to behave much like small versions of the mine drifts, with weeps and halite encrustations forming on the sides and the end. Small stalactites can grow from the top side of the holes, and occasionally brine accumulates on the bottom. In those circumstances where the openings to the holes are restricted and a saturated or partially saturated atmosphere develops in the hole, brine may accumulate on the bottom and eventually seep out at the collar, where salt buildup may develop.

3.1.3 DAMP OR WET AREAS ON FLOORS

Moist areas have been observed on the floor of the workings, but most have been associated with dust-control or other operational activities. Rare occurrences in which brine has seeped from the Salado Formation have been noted. In most

Table 3-2.

instances, such damp areas have been associated with fractures that provide pathways for brine movement. Small puddles, apparently naturally occurring, were observed on the floors of Room J and Room G. The puddles were quickly limited in size by evaporation into the air circulating through the workings and rapidly became crusted over with crystallizing salt. Where the floor is covered with a layer of partially consolidated salt muck, saturation of the layer of muck below the salt crust can exist, but usually goes undetected. The occurrences of damp or wet areas on floors may be considered a special subset of the occurrences in vertical downholes.

3.1.4 ASSOCIATED GAS OCCURRENCES

The BSEP (as discussed in Section 1.3 of this report) is focused on the brine, not the gas, occurrences noted at WIPP. One important observation that has been made during Phase 1 of the BSEP is that gas flow and brine flow appear to be intimately related. As described in Section 3.1.1, small amounts of gas are associated with many weep occurrences on freshly-mined faces. Gas commonly exsolves from solution as the brine is poured from one container to another. Gas is observed bubbling up through many of the brine occurrences. Fractures, commonly measured in fractions of a millimeter in width and a few meters in length (Appendix C), contain gas and brine in sufficient volume and under sufficient pressure to keep the fractures at least slightly open under lithostatic pressure.

The observations document that salt creep closure and two-phase fluid flow are occurring simultaneously, at least in the immediate vicinity of the repository excavations. It is still not clear what effect the coupling of these processes have on brine inflow or repository behavior. The resaturation of the openings which include the spaces within the waste storage areas (between and within waste containers and between any backfill), the access drifts, and the fractures in the salt, are presently being considered in light of the coupling of these processes. Data collected as part of the BSEP will continue to feed those modeling efforts.

3.2 BRINE INFLOWS INTO MINES IN EVAPORITE FORMATIONS

Small volumes of brine are frequently encountered in mines in evaporite formations including both dome salt and bedded evaporites. A literature review was conducted to provide additional background information on the occurrence of brine. This section briefly reviews these occurrences, most of which cause no disruption of mining operations. The focus of this section is on brine occurrences other than those at WIPP. A discussion of sources of brine in the Salado Formation near WIPP is presented in Section 4.1.

3.2.1 Dome Salt

Many mines in Gulf Coast dome salt have experienced brine and gas seeps or inflows. These occurrences have been reviewed by Kelsall and Nelson (1983). Most occurrences of brine or gas in mines in dome salt are small and have had no effect on mining operations. The initial flow rates are generally the maximum flows noted, and they simply decrease until flow ceases. In rare cases, however, brine inflows have required grouting of brine-emitting zones

or caused major floods which sometimes caused the abandonment of drifts or mines. Brine originates in overlying strata, (including the caprock), surrounding formations (intruded by the salt diapir), porous zones in the salt, and overlying bodies of surface water. The brine inflows or seeps reach the mines through boreholes drilled for mining or exploration purposes, fractures in the salt (particularly near the top or edges of the dome), and through structurally controlled permeable zones, such as brecciated fault zones. Movement of brine through the salt may be enhanced by fracturing of the salt and high hydraulic gradients that may exist near dome edges or the caprock.

During brine migration experiments at Avery Island, Krause (1983) reported brine inflows into an unheated site on the same order of magnitude as the brine inflows into heated holes. He measured approximately 0.026 grams of moisture per day flowing into unheated site AB.

Small quantities of gas are probably ubiquitous in dome salt and occur as intragranular or intergranular bubbles. In most cases, gas occurrences in dome salt are associated with argillaceous salt or inclusions of clastic sediment, suggesting the gases were contained within pieces of other sedimentary rocks incorporated into the salt during the rise and intrusion of the salt diapir. More rarely, large, highly pressurized occurrences result in "blowouts" which violently emit large volumes of gas and salt. Blowouts of salt and gas probably occur because of the loss of confining pressure as the result of mining activities (Kelsall and Nelson, 1983).

3.2.2 Bedded Salt

Brine seeps and leaks into mines have occasionally been encountered in the Salado Formation during potash mining operations in the Carlsbad District. Griswold (1977) indicated that the average brine inflow into mines in the area is probably on the order of 40 to 400 liters per occurrence, although he did report an account of one occurrence that yielded over 400,000 liters of brine. Small brine inflows of the magnitude of those in the WIPP excavations are rarely, if ever, reported because they neither present a hazard to personnel nor cause difficulties in routine mining operations. The McNutt potash ore zone, the principal ore-bearing unit in the basin, lies about 200 meters stratigraphically above the WIPP facility horizon. The seeps are allowed to flow until depleted and do not affect mining operations (Register, 1981).

Well-documented data on brine occurrence in bedded salt from the Mississippi Chemical Mine, east of Carlsbad, NM, resulted from experiments investigating brine movement under thermal gradients (brine migration). Some of these experiments recorded data for brine releases in unheated (ambient) conditions. Hohlfelder (1980) reported brine releases occurring during the Salt Block II Experiment prior to heating. Ewing (as reported by Shefelbine, 1982) recorded average inflows ranging between 0.077 and 0.21 grams/day during ambient conditions prior to heating in the three-heater experiment.

Minor gas releases from pressure relief holes drilled into the roof of potash mines, gas flows lasting several months, and work-disrupting blowouts are also recorded in potash mines and in drilling operations in the Carlsbad District (Rutledge and Morgan, 1963, 1964a, 1964b, 1964c; Rutledge, 1964; Rutledge and

Kennedy, 1964a, 1964b; Rutledge et al., 1964; TSC-D-Appolonia, Part II, 1983b; and Chaturvedi, 1984). Some gas releases are also accompanied by brine. Most of these occurrences do not affect mining operations and minor gas inflows such as those described in this report are rarely, if ever, reported. Blowouts are often associated with an obvious, vertical fracture.

Considerable attention was attracted by a series of three gas releases that occurred in the Kerr-McGee (now New Mexico Potash) mine near Carlsbad, New Mexico, in 1983 and 1984, one of which involved a fatality (Cavanaugh and Davidson, 1983; Chaturvedi, 1984). This occurred at a location approximately 15 kilometers north of the WIPP site in the McNutt potash zone in the upper part of the Salado Formation, 200 meters stratigraphically above the WIPP facility horizon. A very small amount of brine, sufficient to dampen the trace of the fracture, was associated with this release. After the release of pressurized gas, an open fracture 5 to 10 millimeters wide and more than 8 meters long was left (Chaturvedi, 1984). This release occurred at a depth of approximately 500 meters below surface. The question of how wide and how long the fracture was prior to the explosive release of gas remains unanswered.

Investigations of the gas occurrences cited above have concluded that most of the occurrences are small and that most of the gas present in the bedded evaporites near Carlsbad resides in clay or argillaceous beds in the salt, with far less residing in polyhalite beds or in the halite. In these studies, gas was most frequently encountered in boreholes drilled upward through the back (roof) at the intersection of drifts. This result supports the idea that the gas accumulates locally in response to the excavation-induced stress redistributions and increased near-field permeability caused by the mining operations. These effects are discussed in more detail in Section 4.2.

No other accounts of brine inflows into salt mines in North America were found in the literature search. Some potash mining has occurred in the Paradox Basin bedded evaporites in the Four Corners area. The Cane Creek Mine was the site of a disruptive, mining-related gas (not brine) release that caused the mine to be converted to a solution mining operation (Westfield et al., 1963). The gas may have originated in a dolomite interbed.

3.3 BRINE OCCURRENCES IN SALADO FORMATION DRILL HOLES NEAR WIPP

Brine and/or gas has also been encountered in the Salado Formation in the vicinity of the WIPP site during drilling for potash evaluations, oil and gas exploration, and various WIPP site characterization studies (Griswold, 1977; Powers et al., 1978; Register, 1981; Popielak et al., 1983; Mercer, 1983; and Mercer, 1987). These occurrences are distinctly separate from those encountered in the Rustler Formation overlying the Salado, and from the "brine reservoirs" in the underlying Castile Formation mentioned in Section 4.1.4 of this report. They are also separate from, but may be more closely related to, the small inflows into the mined repository that are the focus of the BSEP.

Mercer (1987, p. 15) summarizes this data, observing:

> "Very few hydraulic data are available for the Salado Formation. In the halites, the presence of water is restricted because halite does not readily maintain primary porosity, solution channels, or open fractures. Investigations to-date of the Salado Formation at the WIPP site do not indicate an active, circulating, ground-water system."

4.0 PRELIMINARY HYDROLOGIC - GEOMECHANICAL EVALUATIONS

The observations and measurements (summarized in Section 3.1, and presented in detail in Appendices D and E) suggest that multiple brine sources may be involved at the WIPP site and that complex flow induced by excavation is taking place. The potential sources of brine and the flow mechanisms that may be involved are described and evaluated in this section as to applicability at the WIPP repository horizon. Where appropriate, previous relevant scientific investigations are referenced. We emphasize that the observations and measurements have been made in the near-field environment of the underground excavations, which is to be distinguished from the far-field, overall WIPP site hydrogeologic environment.

Moisture does occur in the Salado Formation at the WIPP site. In discussing short-term mining-induced transient flow systems and the rate at which brine flows into the excavations, it may not be important whether the moisture in the Salado is residual from the Permian Sea (connate water), is the result of diagenetic or other processes including dehydration of hydrated minerals, or was introduced into the rocks by some past or present regional flow system. However, the source characteristics (moisture content, permeability, and extent of porous zone) will influence cumulative volume of brine reaching the repository.

Several investigators have measured the moisture content of salt in the Salado Formation. Black et al. (1983) measured a moisture content of 0.59 percent by weight at the repository horizon by heating the salt samples to a temperature of 400°C. The BSEP investigations focus on the water that can and does migrate into the underground openings, which are at atmospheric pressure and approximately 27°C. The migration of brine is probably in response to pre-existing or transient pressure gradients. As a result, the fluid which is locked within unfractured crystals, which is tightly bound to clays or other minerals, or which requires higher than repository temperatures to be liberated, is of lesser concern. Preliminary measurements of the fluid content present in 26 samples from the repository level heated to 250°C is on the order of 0.1 percent by weight, ranging from undetected to a maximum of 0.27 percent (Black et al., 1983). Since heating to 250°C liberates some water of hydration, the actual amount of fluid free to migrate under repository conditions is probably some fraction of those values. Additional measurements of the fluid content of rocks exposed in or occurring close to the repository excavations are presently being made and will be described in a later report.

Similar results were obtained by Hohlfelder (1981), who tested nine samples obtained from the McNutt potash zone exposed in the Mississippi Chemical Mine 19 kilometers northwest of the WIPP site. This is a mineralogically more complex horizon in the Salado Formation that contains more polyhalite than the facility horizon salts. At 200°C, he found that the weight loss ranged from 0.010 percent to 0.044 percent, with the average being 0.028 percent. At 425°C, he found that the weight loss ranged from 0.25 percent to 1.21 percent, with the average being 0.51 percent.

4.1 SOURCES OF BRINE IN THE SALADO FORMATION AT WIPP

Many occurrences of water and brine in evaporite formations, consisting mainly of halite, anhydrite, and gypsum, have been documented. They appear to occur principally as:

- o Hydrous minerals (gypsum, clays),
- o Fluid inclusions in bedded salt (intragranular and intergranular)
- o Intergranular porosity and open fractures
- o Larger porous zones often referred to as "brine reservoirs"

Occurrences of fluid inclusions and hydrous minerals are particularly well-described in the literature. Brine reservoirs have not been as well described, but the literature concerning them is increasing due to the importance of salt formations for siting nuclear waste repositories.

The Salado Formation (described in Powers et al., 1978, and U.S. DOE, 1986) has a complex mineralogy. It is composed of bedded halite with lesser amounts of anhydrite, gypsum, and polyhalite. A detailed geologic description of the repository horizon of alternating layers of halite, polyhalitic halite, and slightly argillaceous halite is provided by Holt and Powers (1986). The halite is generally white to clear, but may be tinted orange, reddish-brown, or gray by interstitial polyhalite or clay. The argillaceous halite is usually reddish-brown in color, with the clay occurring as matrix, interstitial, and intercrystalline material. Halite also occurs as large replacement crystals (pseudomorphs) after gypsum swallowtail crystals and, less commonly, as displacement crystals in some beds of argillaceous halite and anhydrite. Penecontemporaneous dissolution pits, often reaching depths greater than 3 feet, are locally abundant (Powers and Hassinger, 1985) and contain large (1-2 cm), clear halite crystals with frequent fluid inclusions. The halite and anhydrite mineralogy of the WIPP repository horizon has been described by Grim, et. al. (1960) and Stein (1985a). Stein (1985a) reports that the non-NaCl components consist of quartz, anhydrite, gypsum, magnesite, polyhalite, and clays, with traces of alkali feldspar and possibly zeolites. The salt itself contains, on the average, less than 5 percent by weight mineral impurities, except in areas of well-defined anhydrite or clay interbeds.

4.1.1 HYDROUS MINERALS

The most common hydrous minerals (i.e., minerals containing bound water) in evaporite sequences include:

- o Gypsum ($CaSO_4 \cdot 2H_2O$),
- o Clays in mudstone partings and layers, and disseminated in evaporite beds,
- o Several minor hydrous chlorides, sulfates, and carbonates.

Gypsum is a common evaporite mineral that usually dehydrates to anhydrite during consolidation and diagenesis. Most evaporite sequences older than

Tertiary contain anhydrite only, with gypsum being a rehydration product or occurring locally where dehydration was impeded by entrapped brine. One kilogram of gypsum contains over 200 grams (over 1/5 total mass) of water. Clays may be detrital or authigenic and, like gypsum, may release water to the salt when less water-rich clays are produced during diagenesis (Collins, 1975). The hydrous phases in evaporite formations are usually concentrated in individual interbeds, partings, or zones, but they may be dispersed through the salt (Holser, 1979). Gypsum veins may be common locally (Pettijohn, 1975).

The bound water in hydrous minerals is located in specific sites in the minerals' crystal structure. As such, bound water is not a significant source for brine flows. Dehydration of these minerals during burial, heating, compaction, and diagenesis may be a source of water that, if retained in the sediments, may be entrapped in inclusions and brine reservoirs.

4.1.2 FLUID INCLUSIONS

Bedded salt is known to contain up to 1.7 percent water in the form of fluid inclusions (Roedder and Belken, 1979; Roedder, 1984). Fluid inclusions are isolated pockets of brine measuring up to several millimeters in diameter occurring within (intragranular) or between (intergranular) halite crystals. Intragranular occurrences are usually crystallographically controlled and are frequently cubic in shape. Large inclusions tend to be more irregular. The enclosed brine is generally a saturated aqueous NaCl solution that usually includes other cations (Ca, Mg, K) as well as organic compounds and dissolved or exsolved gasses (Roedder, 1984).

An extensive review of the occurrences and geochemistry of fluid inclusions in salt is given by Roedder (1984). Fluid inclusions may be primary (i.e., trapped during the original deposition of the enclosing halite) or secondary, forming after original deposition. Secondary fluid inclusions may form either under near-surface sedimentary conditions, during diagenesis or recrystallization of the primary halite, or during deformation of the evaporite beds. The secondary fluid inclusions may enclose connate brine (syngenetic interstitial water), but the brine may be altered by mixing with other water sources. These sources include both waters of dehydration of hydrated mineral phases and groundwater introduced into the salt. Inclusions may be concentrated in certain horizons or may occur in thin (10's to 100's of micrometers) bands within the salt. Intergranular inclusions probably indicate recrystallization of the salt sometime following original deposition (Roedder, 1984).

The origin of fluid inclusions may be indicated by the geochemistry of the trapped fluid as well as by petrographic details. Disparate fluid compositions among trapped brines in a given unit are frequently noted even between inclusions in close proximity. Some fluid inclusions may contain connate brines while others really contain brines that are the product of mixing or rock-brine interactions (Roedder, 1984). Stein (1985a), and Stein and Krumhansl (1986) have made preliminary studies of fluid inclusions present in the Salado Formation at the WIPP site. Most of the inclusion fluids studied were extracted from the larger, recrystallized halite crystals described in Section 4.1.

Estimates of the amount of brine contained in fluid inclusions at the repository level range from 0.22 weight-percent (Black et al., 1983) to about 0.6 weight-percent (Stein, 1985b). Stein and Krumhansl (1986), came to the preliminary conclusion that the chemistry of the fluid inclusions and the chemistry of the weep and drill hole fluids differed sufficiently to suggest different origins. Additionally, the brines contained within fluid inclusions are not free to migrate into underground openings under a pressure gradient until such inclusions are intersected by fractures, hence the inclusion fluids are not a primary focus of the BSEP.

4.1.3 INTERGRANULAR POROSITY AND OPEN FRACTURES

Brine occurs in the salt of the repository horizon both in hairline fractures, along grain boundaries, and in larger fractures that cut through grains. The latter are much more significant in terms of brine movement through the salt, as some have been observed to be in locations where brine seeps into the underground openings. Fractures up to a few millimeters in width have been observed in freshly excavated surfaces at the facility horizon, 655 meters beneath the surface (Appendix C). The brine is associated with gas, both of which are pressurized and may be responsible for keeping the fractures open prior to mining. It is difficult to obtain good values for the permeability of the porous zones and open fractures in the Salado Formation.

Conventional drill-stem tests performed at WIPP-associated wells generally found that the permeability of the Salado Formation in the vicinity of WIPP was less than the sensitivity limit of the system, i.e., less than 1×10^{-7} darcy. Beauheim et al. (1983) reported field permeability values for the Salado Formation at Cabin Baby-1 of about 9×10^{-9} and 8×10^{-8} darcies, but expressed concern over data interpretations. Specialized testing obtained qualified values in the range of 2.1×10^{-5} to 2.5×10^{-5} darcies for the bulk permeability of the Salado (Peterson et al., 1981; Mercer, 1987).

Peterson et al. (1985) report the results of permeability tests made in the facility horizon at WIPP using pressurized gas. The interpreted data indicated permeabilities ranging from about 10^{-6} to less than 10^{-9} darcies for undisturbed salt. It should be noted that these values were calculated assuming an unsaturated pore volume. As the authors pointed out, "If the volume were partially or fully saturated, so that fluid migration and/or threshold pressure effects were important, the intrinsic formation permeability would be larger than reported."

As discussed in more detail in Section 4.2 below, excavation-induced stress redistributions may cause the permeability of the Salado Formation to increase or decrease with time. The Peterson et al. (1985) field data from the repository level also supports the theoretical prediction that a disturbed zone with increased permeability will develop adjacent to the repository excavations. Conversely, it is possible that at depths comparable to the waste repository and at some distance from the excavation itself, the high lithostatic pressure in combination with brine moisture will likely result in the healing or sintering of open fractures and in the isolation of zones that might yield moisture to the repository excavations. Such fracture healing may also occur after repository closure, sealing, and repressurization. This is discussed further in Section 4.2.1.1.

Brine inflows into the local potash mines were discussed in Section 3.2.2, and are generally of greater total volume than those observed at WIPP. These occurrences are associated with the McNutt potash zone, stratigraphically higher and more complex mineralogically than the WIPP facility level. These inflows occur at shallower depths than at WIPP; it would be expected that the rocks in those mines are subjected to lower lithostatic stress. Greater values for porosity and permeability would be expected in the potash zone in those mines than at the repository horizon at WIPP. The possibility of recharge from the surface may also be more likely near some of the mines.

As previously described, the bedded salt deposits at WIPP contain relatively thin interbeds of anhydrite and clay. These interbeds contain brine in porous zones or open fractures as described above for the salt. They probably have different permeabilities and porosities from the salt and have a strong local effect on both the volume of brine available and the brine flow path.

Brine may occur in interstitial porosity in interbeds or in a fracture system within brittle interbeds, such as anhydrite. Hydrogeologic evidence for brine occurrence in anhydrite Marker Bed 139 was developed by Borns (1985) who described the structure of the marker bed in several zones. In one zone where anhydritic laminae were present, horizontal fractures were found. These fractures were in-filled with polyhalite and halite, indicating past movement of brine through them.

4.1.4 LARGE FRACTURED ZONES ("BRINE RESERVOIRS")

Large fractured zones capable of producing large volumes of brine (millions of liters), referred to as "brine reservoirs," have been encountered while drilling through evaporites in the Permian Basin. A comprehensive study (TSC-D'Appolonia, 1983c) of brine reservoirs in the underlying Castile formation at the WIPP site concluded that the reservoirs occurred in massive anhydrite layers approximately 100 meters thick that had been deformed upward by the underlying salt. The brine-producing zones encountered during drilling are interpreted as a lateral system of open fractures that provide an initially vigorous flow or pressure buildup response, combined with a system of microfractures that provide a slower sustained response.

There is no evidence to indicate that large fractured zones such as these occur in the Salado Formation in proximity to the repository horizon to affect the small, near-field brine inflows discussed in this report. Additionally, the Castile brine reservoirs are stratigraphically isolated from the WIPP repository by more than 230 meters of intervening evaporite beds. At the repository horizon the anhydrite beds in the Salado are much thinner than those in the underlying Castile Formation. There is also no evidence of salt anticline development at the repository horizon that seems to be associated with the large brine producing zones. It is concluded that the source of brine at the repository horizon is not a large-scale brine reservoir.

4.2 BRINE FLOW MECHANISMS

The observations of brine and the brine inflow measurements made previously (Section 3.0) are related to the excavation of an underground repository.

Flow may occur under a hydraulic gradient or under a thermal gradient. Flow may develop through salt and through the anhydrite and clay interbeds. The preliminary data from the BSEP indicate that no single simple set of conditions exists. The observed brine inflows almost certainly reflect a combination of the mechanisms discussed below. The combination of these mechanisms varies in both time and space.

4.2.1 FLOW UNDER A HYDRAULIC GRADIENT

In describing the fluid-flow systems operational under a hydraulic gradient, several stages in the development of the repository are identified by Freeze (1983) (Figure 4-1):

- Undisturbed flow regime prior to excavation (Stage 1)
- Transient flow regime during repository excavation and operations (Stage 2)
- Steady-state flow regime during repository operations (Stage 3)
- Transient flow regime during repository resaturation (Stage 4)
- Restoration of hydraulic gradients (Stages 5 and 6)

The first three stages are described below.

Prior to repository construction, there will be an initial steady-state hydraulic potential distribution in the vicinity of the repository (Stage 1). The flow in the undisturbed state could occur both vertically and laterally through the salt, clay interbeds, and interbeds of fractured anhydrite.

The quantity and rate of fluid movement through the Salado Formation under pre-excavation regional hydraulic gradients is small to nonexistent, and is probably not a significant factor in the mechanisms causing the observed inflows into the repository. Moisture does, however, occur in the Salado Formation (Section 4.1). For the purposes of the following discussions of short-term mining-induced transient flow systems, the source of that moisture may not be important, although it may have implications on reservoir characteristics that might determine the total volume of brine that is available for migration into the repository.

During repository construction and operation, a transient flow system (Stage 2) will be set up with flow towards the repository in response to the constant pressure drawdown that occurs at the excavation surface and the increase in permeability caused by stress redistribution near the excavation. Inflows may be evaporated and removed from the excavations by the ventilation system. If the repository is in operation long enough, inflows may become steady-state (Stage 3). If hydraulic gradients become smaller, the flow becomes non-Darcian, or a region develops around the repository where permeability is reduced from pre-excavation values, then inflow may be reduced or cease completely.

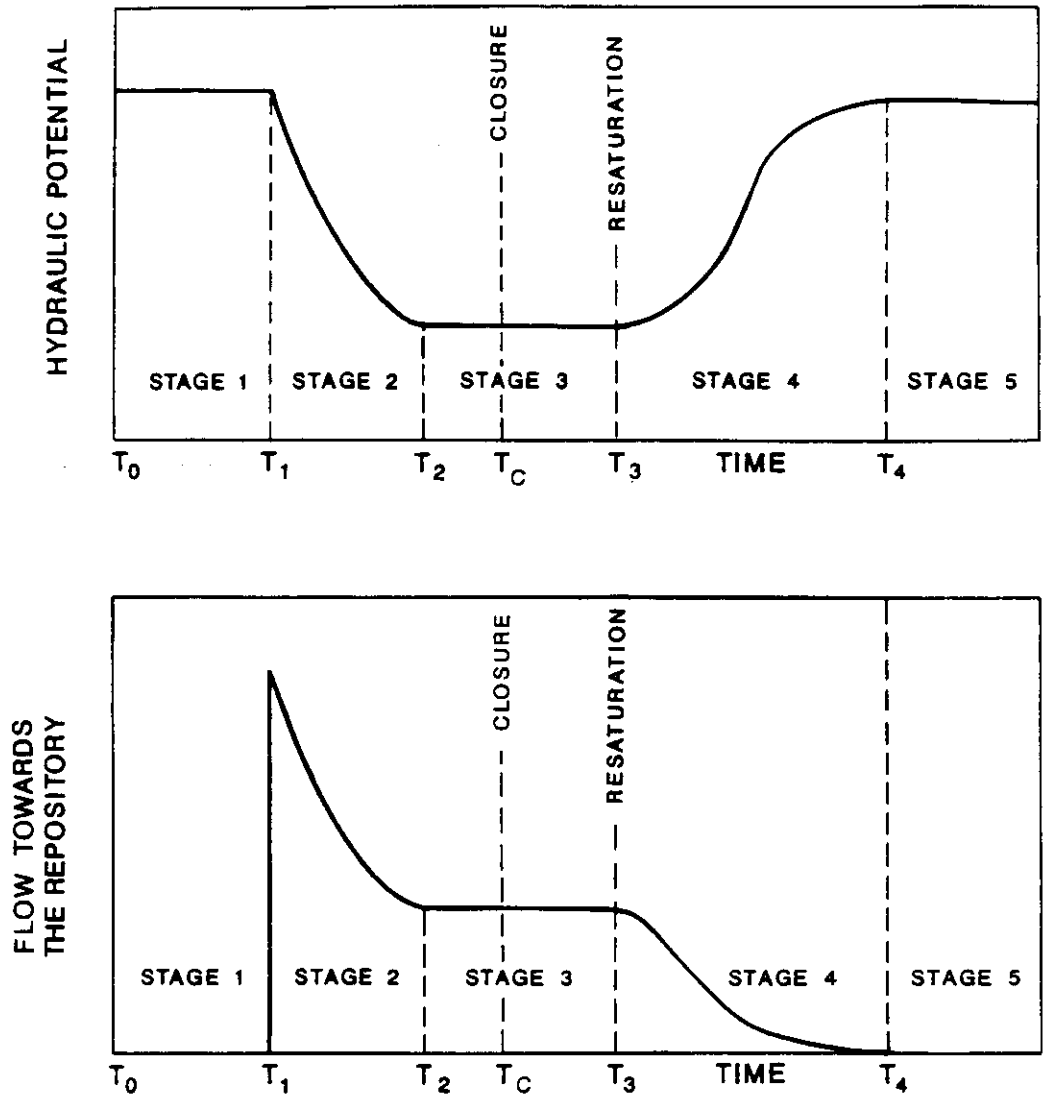

Figure 4-1.

Conceptual Model for Brine Flow Towards a Repository
(Modified From Freeze, 1983)

The following discussion addresses flow during repository operations through both undisturbed salt and interbeds (Stage 1) and flow through disturbed salt and interbeds in the vicinity of the excavation (Stages 2 and 3). Disturbance encompasses both the effects of constant pressure drawdown and lithostatic stress relief. Several fluid-flow systems under a pressure gradient are then described.

4.2.1.1 Flow Through Salt

Brine may flow through either the intercrystalline or intracrystalline structure of salt. Owing to the relatively low permeability of individual salt crystals, fluid inclusions within individual crystals may move very slowly, whereas fluid movement occurs more rapidly in the intercrystalline structure of the salt. Case and Kelsall (1985) compiled laboratory and field data which show that the permeability of salt under a wide range of confining pressure ranges from 1 md to 10^{-6} md, while the measurement of the permeability of a single salt crystal was 10^{-9} md (Sutherland and Cave, 1980). It is noted by some investigators (Remson, 1984) that flow rates calculated using traditional transport equations may be too high. We suggest that this may be because the brine exists as a thin film surrounded by a massive salt matrix and that surface forces may become dominant in affecting interstitial flow. The proportionality between flux rate and hydraulic gradient (Darcy's Law) may no longer apply and the flow will occur at a much slower rate. For practical purposes, the brines may be immobile [as suggested by geochemical analysis (Popielak, et al, 1983)], although this immobility has not been proven by hydrologic observation or analysis.

During excavation of the underground facility, the local hydraulic gradient is increased, resulting in brine flow from the adjacent strata to the excavation. Stresses are redistributed in the salt fabric resulting in an increase in permeability. Both these processes would result in an increased brine flow rate. Conversely, as interstitial pressures are relieved, there is compression of the pore space and accelerated creep due to increased effective stress[1]. This, in conjunction with the reduction of the hydraulic gradient with time, will tend to reduce brine inflow rates.

Theoretical studies (Kelsall et al., 1982 and Case and Kelsall, 1985), and field measurements (Peterson et al., 1985) support the existence of a zone of increased permeability as illustrated in Figure 4-2. In the radial direction from the room, the stress has been relieved, resulting in an increase in permeability normal to this direction (Figure 4-3). In the tangential direction, the stresses may increase initially at the room boundary due to the elastic response, and then decrease due to inelastic creep deformations. The permeability may increase or decrease normal to this direction (Figure 4-3).

[1] Effective stress is used in this context as the difference between total stress and pore pressure.

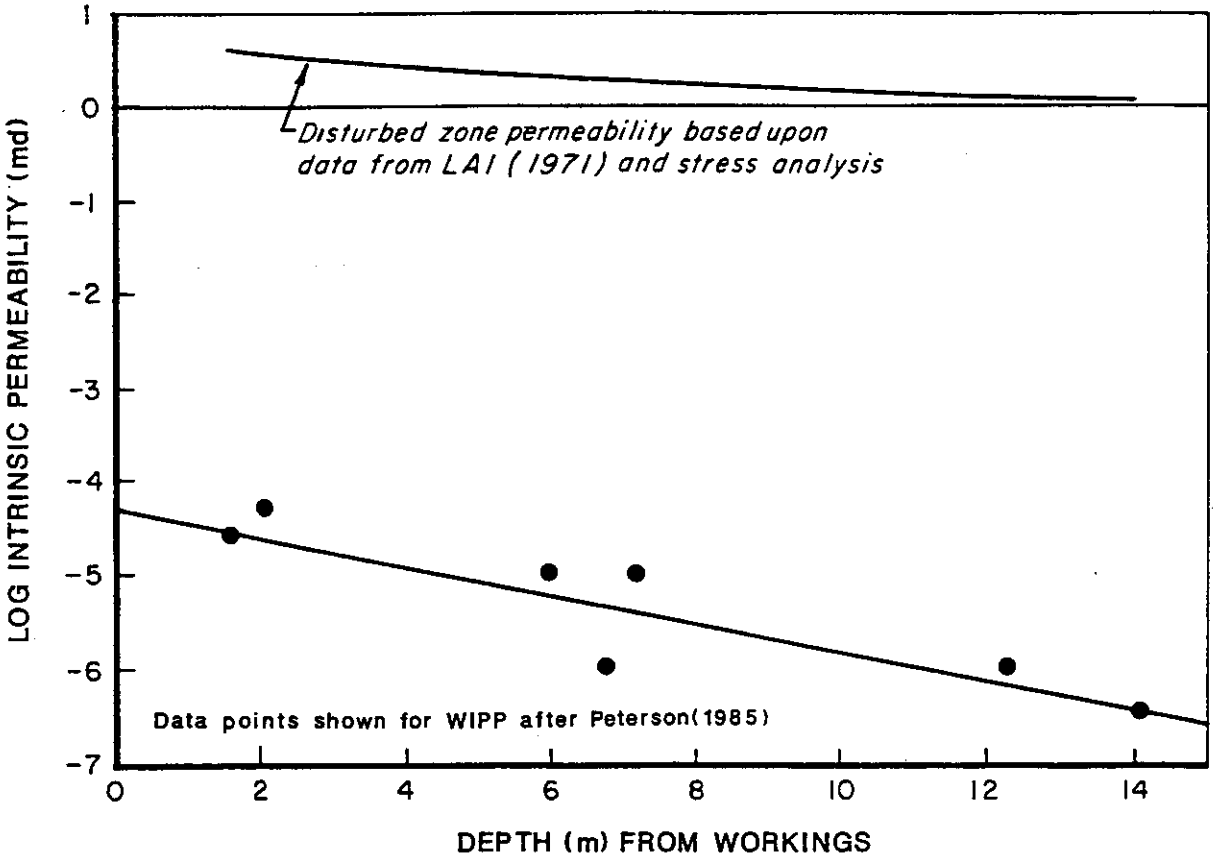

Figure 4-2.

Relationship of Salt Permeability and Depth Near an Excavation
(From Case and Kelsall, 1985)

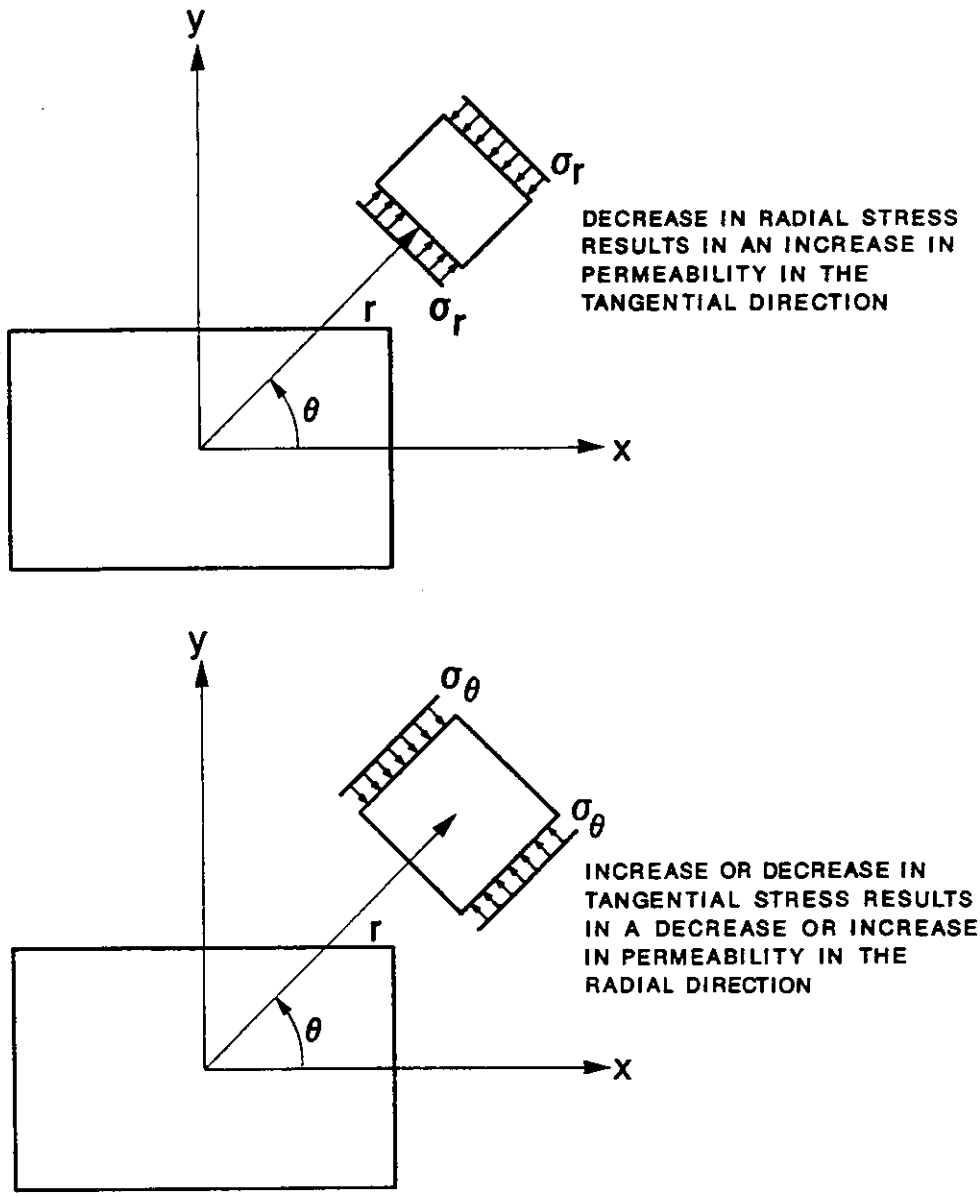

Figure 4-3.
Modification of Permeability in the Radial and Tangential Directions

This modified permeability zone ("disturbed zone") occurs in the immediate vicinity of the excavations and has a width that increases with time, beginning immediately with the excavation of a new opening and continuing until repressurization after closure. In a practical sense, this zone may extend from a few meters to a few tens of meters away from the repository. Evidence regarding this change in permeability around an entry has been obtained using a guarded straddle packer system (Peterson et al., 1985). The tests were performed to determine the permeability of salt, the variation with distance from the mined surface, and the influence of interspersed anhydrite and clay seams. The combined permeability measurements indicate that there is a relationship of permeability with test interval depth. The data indicate that permeability is increased from undisturbed values by two orders of magnitude (10^{-6} to 10^{-4} md) within one to 14 meters of the excavation. This trend is similar to that predicted by Kelsall et al. (1982). Since measurements are made for flow normal to the direction of stress relief, the results are not unexpected.

Predictions of the zone of increased permeability at WIPP are made using the stress-permeability relations developed by Lai (1971). Estimates of the amount of stress relief as a function of depth from the rectangular entry may be made using the relationships developed by Chabannes (1982). Assumptions or simplifications include: 1) that the stress distribution is steady-state, and is based upon the steady-state creep law; 2) that the cross-section of the excavation is circular in a homogeneous stress field; and 3) that the far-field stress is hydrostatic. The predicted results show a trend similar to the in situ data; the calculated values of permeability are four to five orders of magnitude higher. The in situ test results indicate steeper changes in permeability with depth than the predictive analysis. Because the actual stress distribution is probably not steady-state, the excavations are not cylindrical, and other assumptions made for the calculations only approximate actual repository conditions, this difference is not unexpected.

Permeability will also increase due to localized fracturing of intact salt, especially in the disturbed zone (Bechtel National, 1986). In Room 2, a single hole NG252 (Appendix D, Section 3.2.2) which was drilled downward for geomechanical instrumentation has produced a relatively large amount of brine. Brine and gas flow into the hole from a fracture located near the base of the anhydrite Marker Bed 139. As described by Bechtel National (1986), the fractures intersect the interbeds and the salt in the disturbed zone. This fracture or a related fracture is observed in the floor of Room 2, approximately 15 meters from the geomechanics instrument array. It is exposed approximately two meters from the west wall of Room 2 and is observed to extend to almost a meter below the surface to the east. It is expected that this type of fracturing will result in a fracture porosity and permeability in the disturbed zone in the immediate vicinity of the repository that is higher than the laboratory or field measurements described above.

Owing again to the relatively low permeability of individual salt crystals, fluid inclusions within individual crystals may move very slowly, whereas fluid movement occurs more rapidly in the intercrystalline structure. It is postulated that intercrystalline brine flow is primarily responsible for the efflorescence that is common throughout the repository.

Tests to evaluate healing of fractured WIPP salt under renewed confining stress have been conducted by Costin and Wawersik (1980) and by Withiam et al. (1984). Costin and Wawersik took short rod specimens fabricated from intact WIPP salt and loaded these specimens to failure creating a fracture along the axis of the specimen. After fracturing, the specimens were pieced together and subjected to higher temperatures (up to 100°C) and pressures (up to 35MPa) in order to "heal" the fractures. The specimens were then retested to determine the degree of fracture healing. The results indicated that 70 to 80 percent of the original strength was recovered within several days. In more recent permeability tests, Withiam et al. (1984) recovered samples from one foot below the repository horizon and created fractures either by sawing or tensile splitting. The fractures created with a bandsaw were smooth, with no discernible roughness. Fractures created by splitting followed crystal boundaries and cleavage faces, and had a typical roughness amplitude in the range of 5 to 10 mm. Permeability tests were conducted at hydrostatic pressures up to 3,000 psi at room temperature. It was concluded that the reduction of permeability with time, under constant confining pressure, suggested fracture healing.

Laboratory investigations have also established the stress dependency of permeability for intact salt through microfracture healing and reduction in porosity (Sutherland and Cave, 1980). A reduction in porosity and permeability due to salt creep could be a significant factor in limiting the inflow of brine into the repository. We hypothesize that flow of brine and gas toward the repository from the interstitial voids and fractures in undisturbed salt will reduce interstitial pressure, allowing salt creep to close void spaces and increase the tendency for fractures to heal. This may result in lowered porosity and permeability in a zone around the repository outside of the zone of increased permeability discussed above. These effects may, in time, reduce or limit the brine inflow. If this occurs, and a permeability barrier develops naturally around the repository, then it follows that air circulating for a sufficiently long period of time during operations prior to closure of the repository will dry out the workings and slow down the process of resaturation after closure.

The establishment of steady-state flow (Stage 3) through salt would be dependent on the hydrologic characteristics of the salt. Owing to its low permeability, the time frame that the repository is operational, and the nature of recharge, steady-state flow might not be established. The occurrence of brine with dissolved gas in isolated fractures or porous zones in salt may also affect the development of steady-state flow. Before excavation, the fluid pressures in fractures is theoretically equal to the lithostatic state of stress, which at the WIPP repository horizon is approximately 15 MPa. During excavation, the state of stress in the salt near the brine occurrence is relieved. The reduction in stress may result in microfracturing of salt at the excavation-brine/gas occurrence boundary and a flow of brine (and gas) into the underground workings can occur. In such a situation, the brine/gas flow is reduced as the fracture or porous zone is drained.

4.2.1.2 Flow Through Interbeds

Because most interbeds create nearly planar discontinuities, flow paths along or through them tend to be less tortuous than flow paths through massive halite. As a result, flow paths associated with interbeds may provide relatively high permeability zones that may effectively collect intercrystalline fluids and provide a route for brine movement toward the repository. During excavation, a high hydraulic pressure gradient is established and flow may occur where an interbed is intersected by a borehole in the repository. Adjacent to an excavation, the permeability of interbeds may be increased by stress relief, especially if flow is occurring in fractures. Fracturing in the disturbed zone in the immediate proximity to the workings could also occur and provide a route for flow through the salt from an interbed (above the roof or below the floor) to the excavation. Separations on the order of several centimeters have developed in and along interbeds (especially associated with brittle anhydrite zones), many months after excavation (Bechtel National, 1986). Considering flow to a borehole, flow may be greater from interbeds which are close to the roof or floor of the excavation in the zone of maximum stress relief.

Indirect evidence for the effects of excavation may be found by comparing the borehole flow measurements in Rooms A1, A2, A3, 1B, and G. As mentioned previously, the anhydrite Marker Bed 139 is located at a greater depth (seven meters) in Rooms A1 through B. The flow measurements in four floor holes in these rooms form a consistent set of measurements, suggesting that the source of the flow for the four holes is the same relatively undisturbed stratum or series of strata. In contrast, the range of recorded inflow rates in Room G is much wider, perhaps reflecting disturbance, different sources of flow, different flow systems, or more local variability in the geology. For example, the two floor holes that are two meters apart, DH42 and DH42A, exhibit distinctly different flow rates and time rates of change in flow rate.

4.2.2 FLOW UNDER A THERMAL GRADIENT

The migration of brine fluid inclusions may develop along a thermal gradient. In this mechanism, the solubility of salt is temperature-dependent with dissolution occurring on the high temperature side and precipitation on the low temperature side. The fluid inclusion moves toward the higher temperature. In general, migration rates are controlled by temperature, temperature gradient, inclusion shape and size, and the salt crystal microstructure (Olander; 1984, 1985).

There is much experimental evidence for brine migration toward a high temperature source (comparable to a radioactive heat source) [Hohlfelder and Hadley (1979); Gnirk et al., (1981); Jenks and Claiborne (1981); Pigford (1982); Olander (1984, 1985); Olander et al (1982); Roedder (1984) and Clark (1985)]. Roedder (1984) states that there is no evidence of brine migration under normal geothermal gradients. In the underground repository, there is an approximate equilibrium between rock temperature and the repository air temperature, with perhaps a slight rise of temperature into the rock. Any tendency for brine to migrate up-gradient would be overshadowed by relatively high hydraulic gradients resulting in flow toward the repository.

5.0 BRINE SAMPLING AND EVALUATION PROGRAM: CONTINUING EFFORTS

The following investigations are continuing as part of the Brine Sampling and Evaluation Program at WIPP. The results will be presented in later BSEP reports.

- Additional delineation of stratigraphic variations in the brine occurrences.
- Additional delineation of horizontal variations of brine content in the rocks exposed at the facility level.
- Refinement of the data on the loosely-bound brine available for non-thermal migration into the repository.
- Characterization of the chemistry of the naturally-occurring brine that is likely to migrate into the repository.
- Continued monitoring of brine inflow into selected drill holes.
- Continued assessment of the feasibility of using geophysical techniques to define source horizons and the aerial extent of brine occurrences at the repository level.

6.0 SUMMARY

Although the WIPP underground constitutes "dry" workings, small amounts of brine are present, probably on the order of 0.1 to 0.5 percent by weight of the surrounding rocks. Part of that brine can and does migrate into the repository openings in response to transient or pre-existing pressure gradients, independent of thermal gradients. These small volumes of brine have little effect on the day-to-day operations, but are pervasive throughout the repository and may contribute enough moisture over a period of years to merit consideration with regard to resaturation and repressurization.

The inflows that occur as "weeps" on the exposed surfaces have been observed since the initial excavations in 1983. "Weeps" are very small inflows of brine that occur on almost all exposed surfaces and are evidenced by halite efflorescence. Small brine inflows also occur in drill holes. Over 1400 drill holes, most 15 meters or less in length, exist in the WIPP underground. Small quantities of gas are often associated with brine inflows. Gas bubbles are observed in many of the brine occurrences. Gas is also known to exsolve from solution as the brine is poured from container to container.

Measured occurrences have inflow rates that range from less than the rate at which surface moisture is evaporated into the repository atmosphere to approximately 0.5 liters per day. Individual occurrences vary greatly and some drill holes separated by less than a meter have inflows that contrast dramatically, making the discussion of "averages" or "typical occurrences" difficult or misleading. The reasons for this variability are still poorly understood. The inflow at any specific location is influenced by a number of factors, including local stress distribution, local brine sources, variations in local fracturing and permeability, and local variation in the geology. Most occurrences displayed a brief, initial no-flow or low-flow period, followed by maximum inflow. Brine inflow then decreased over a period of several months to relatively steady-state conditions. Some occurrences had increased inflows and some ceased entirely. Most of the noticeable inflow rates range between a few tenths and a few hundredths of a liter per day. The largest individual production measured during this reporting period produced an aggregate over 235 liters of brine, and continues to produce over 0.2 liters per day. It was clearly an unusual and exceptional occurrence and was associated with excavation-induced fracturing. Inflow rates in that drill hole have declined markedly over the observation period.

It should be noted that the brine occurrences discussed here are small and are clearly distinguished from the "brine reservoirs" found in the underlying, stratigraphically lower, and geologically older, Castile Formation in the Delaware Basin. "Brine reservoirs" are measured in hundreds of thousands of liters, flow readily into boreholes that penetrate them, and have been the subject of other investigations (Section 4.1.4).

It is clear from the preliminary data that brine inflow, gas inflow, and salt creep into the workings are intimately associated with each other and that significant pressure-driven brine inflows that are not the result of brine migration in a thermal gradient may occur after sealing and closure of the

repository. Brine flow systems are not well understood at this time, but it is likely that the observed inflows are dominated by the response to transient pressure gradients resulting from the excavation of the repository. A component due to regional hydraulic head cannot, at this time, be ruled out.

Brine chemistry data has been collected, but is not reported in this document. Characterization of the near-field brine chemistry continues, and will be included in a future BSEP report.

The major observations may be summarized as:

- Brine inflows are small, and are not related to large brine reservoirs in the Castile Formation.
- Brine occurrences, particularly those evidenced as halite efflorescence, are pervasive throughout the WIPP underground workings.
- Brine inflow rates are low, usually on the order of a few hundredths of a liter per day or less.
- Although small when measured in terms of liters per day at any given location, cumulative inflow volumes may be significant when measured in terms of the entire repository over periods of many years.
- There is a considerable variation in brine inflow between locations, even when locations are only a few meters (or, in some instances, less than a meter) apart.
- Holes that penetrate the roof and floor generally show a pattern of an initial, maximum flow rate that reduces to a fairly steady flow rate over the time period during which measurements have been made.
- Several flow systems and conditions are possible, but insufficient data exist to select the system and conditions (or combination of several systems and conditions) that best describe the phenomena at WIPP.

APPENDIX A

PRELIMINARY INVENTORY OF UNDERGROUND DRILL HOLES AT WIPP

EXPLANATION OF FIELDS USED IN THE DATA BASE FOR APPENDIX A and B

Hole Number

This is the designation number that was assigned to the drill hole. A question mark in the hole number field indicates that the number used was an arbitrary number used on a temporary basis by field personnel for a drill hole actually located underground. Additional checking is necessary to unambiguously determine the assigned number.

Room

Room name or number, if the hole is located in a test or experimental room.

North-South and East-West Coordinates

Mine coordinates of the drill hole collar, in feet, referenced to the center of the C&SH Shaft.

Elevation

Elevation of the drill hole collar, in feet, referenced to mean sea level.

Accuracy

Accuracy of the coordinates and elevation data

- A = Approximate
- B = As-Built survey data
- P = As-Planned location data
- D = Duplicate hole record or record of a hole number that should be deleted from the listing of holes. This is usually the result of both a hole number and a separate instrument number being assigned to the same location.

Purpose

The reason the hole was drilled.

- Ae Acoustic Emission
- C Core

CON Construction-related drilling

CS Clay-seam sample

DD Demonstration drilling

EX Experiment

GT Gas Testing

HF Hydrofrac Experiment

HTR Heater installation

I Instrument

ID Instrument demonstration

LT Lab-testing sample

O Observation hole

P Pilot hole

Pr Pressure-relief hole

RM Rock mechanics

ST Stratigraphic analysis

US Ultra-sonic experiment

WO Water observation

Direction

General direction of the hole from the underground workings: up, down, north, south, east, or west.

Angle

Angle from the horizontal

Depth

Depth of hole in feet, referenced to the collar.

Diameter

Diameter of the hole in inches.

APPENDIX B
LIST OF UNDERGROUND DRILL HOLES WHERE BRINE OCCURRENCES WERE OBSERVED AND MONITORED FOR PHASE I OF THE BRINE SAMPLING AND EVALUATION PROGRAM AT WIPP.

Hole Number	Room	Location Accuracy S=Survey A=Approx	N-S Coord	E-W Coord	Elevation	Dia. (in)	Depth (ft)	Direction	Angle	References	Remarks Brine,gas and general.
A1X01	A1	S	N1147.02	E1254.40	1313.26	4	49.75	D	90	B, D, E	Monitored as part of the BSEP since it was drilled in 3/85.
A1X02	A1	S	N1146.88	E1254.24	1331.29	4	59.0	U	90	B, D, E	Monitored as part of the BSEP since it was drilled in 3/85.
A2X01	A2	S	N1393.72	E1338.88	1311.20	4	50.15	D	90	B, D, E	Monitored as part of the BSEP since it was drilled in 2/85
A2X02	A2	S	N1393.65	E1338.89	1328.86	4	52.75	U	90	B, D, E	Monitored as part of the BSEP since it was drilled in 2/85.
A3X01	A3	S	N1137.94	E1406.84	1309.78	4	50.5	D	90	B, D, E	Monitored as part of the BSEP since it was drilled in 1/85. Drillers did not report any moisture while drilling. Hole started producing brine few weeks later.
A3X02	A3	S	P1138.00	E1406.89	1327.93	4	50.75	U	90	B, D, E	Monitored as part of the BSEP since it was drilled 1/85. Drillers did not encounter moisture while drilling. Hole started producing brine few weeks later.
BX01	B	S	N1384.68	E0982.33	1317.44	4	50.15	D	90	B, E	Monitored as part of the BSEP since it was drilled in 1/85.
BX02	B	S	N1384.44	E0982.87	1335.47	4	49.25	U	90	B, E	Monitored as part of the BSEP since it was drilled in 1/85.
DH035	G	A	N1102	W1882	1294.4	3.5	52.0	U	90	A3, B	Monitored as part of BSEP since 2/85.
DH036	G	A	N1102	W1882	1284.6	3.5	51.5	D	90	A3, B	Monitored as part of BSEP since 1/85.
DH037	G	S	N1101	W2182	1297.4	3.5	51.5	U	90	A3, B	Monitored as part of BSEP since 1/85. At the present no brine is collected because of insufficient inflow.
DH038	G	S	N1101	W2182	1287.0	3.5	47.5	D	90	A3, B	Monitored as part of BSEP since 1/85.
DH039	G	S	N1101	W2482	1296.0	3.5	50.7	U	90	A3, B	Monitored as part of BSEP since 2/85. At the present no brine is collected because of insufficient inflow.
DH040	G	S	N1101	W2482	1286.1	3.5	51.0	D	90	A3, B	Monitored as part of BSEP since 1/85.
DH041	G	S	N1101	W2782	1295.8	3.5	49.9	U	90	A3, B	Monitored as part of BSEP since 2/85. At the present no brine is collected because of insufficient inflow.
DH042	G	S	N1101	W2782	1285.9	3.5	51.2	D	90	A3, B	Monitored as part of the BSEP since 2/85.
DH042A	G	S	N1101	W2789	1285.7	3.5	40.5	D	90	A3, B	Monitored as part of the BSEP since 2/85.
DH215		S	S1960	E0153	1272.0	3	52.0	U	90	A1, B	Gas releases had been observed in this hole. Monitored as part of the BSEP since 1/85.
DH216		S	S1960	E0153	1262.6	3	54.2	D	90	A1, B	Gas releases had been observed in this hole. Monitored as part of the BSEP from 1/85 to 6/85.
DH317		S	S1600	W0033	1271.3	3	50.1	U	90	A2, B	Stalactite growth monitored as part of BSEP from 05/07/85 to 01/31/86.
DH317A		S	S1600	W0030	1271.2	3	5.0	U	90	A2, B	Stalactite growth monitored as part of BSEP from 05/07/85 to 01/31/86.
DH317B		S	S1597	W0030	1271.2	3.5	51.0	U	90	A2, B	Gas pocket at 45.91. Brine seeped from hole after drill rods were broken at end of run at depth of 16.3 ft. Probable source was anhydrite "a". Monitored as part of BSEP from 05/07/85 to 01/31/86.
IG201	2	S	N1275.54	W0379.51	1294.97	2.875	53.83	D	90	A3, B, H, J	Monitored as part of BSEP since 11/84.
IG202	1	S	N1264.79	W0246.11	1296.49	2.875	48.16	D	90	A3, B, H, J	Monitored as part of BSEP since 11/84.
JV8	J	S	N1067	W0374	1290	36	8.1	D	90	D, F, G	Drilled 8/08/85, drillers reported water at 7 ft 10 inches.
JV9	J	S	N1067	W0378	1290.4	36	8.1	D	90	D, G	Brine in bottom of pilot hole on 8/20/85.
L1S25	L1	A	N1524	W0218	1312	4	11.90	D	90	B, H	Monitored as part of BSEP since 12/10/85.
L1S26	L1	A	N1524	W0220	1312	4	11.72	D	90	B, H	Monitored as part of BSEP since 12/10/85.
L1S27	L1	A	N1524	W0222	1312	4	11.93	D	90	B, H	Monitored as part of BSEP since 12/10/85.

APPENDIX C

GAS OCCURRENCES AT THE MINING FACE IN THE WIPP REPOSITORY EXCAVATIONS, MARCH AND APRIL, 1986

by Richard Deshler
IT Corporation

A review of WIPP mining operations shift reports has been made for any documented occurrences of gas at the mining face which were described as "audible" releases prior to March 21, 1986. Only two such documented occurrences were noted. These were reported on February 6, 1983, in the face at E0, N800, and on April 1, 1984 in the C2 alcove.

There were several reports of gas releases from holes drilled into the roof of the facility. This type of occurrence is not uncommon at WIPP and only those occurrences considered anomalous are reported here.

The only notable cases of gas encountered in the face were those which occurred during mining activities in the S2180 area during March and April of 1986. None of these resulted in any personnel injury or property damage. These encounters are described below:

1. A small release occurred during mining in the S2180 drift at about E233 on March 21, 1986. The same day, a horizontal probe hole drilled ahead of the face also encountered gas.

2. A pressure relief hole drilled into the roof of the S1950 and E300 intersection in December, 1985 began venting <u>during mining</u> to the south of this intersection on April 7, 1985. In addition, a small release was noted in the horizontal probe hole in the E300 drift on April 2, 1986.

3. A small release occurred in the face during mining in the E300 drift at about S2140 on April 9, 1986.

REPORT OF GAS OCCURRENCE

Location: S2180 Drift Between E140 and E300

Date: March 21, 1986

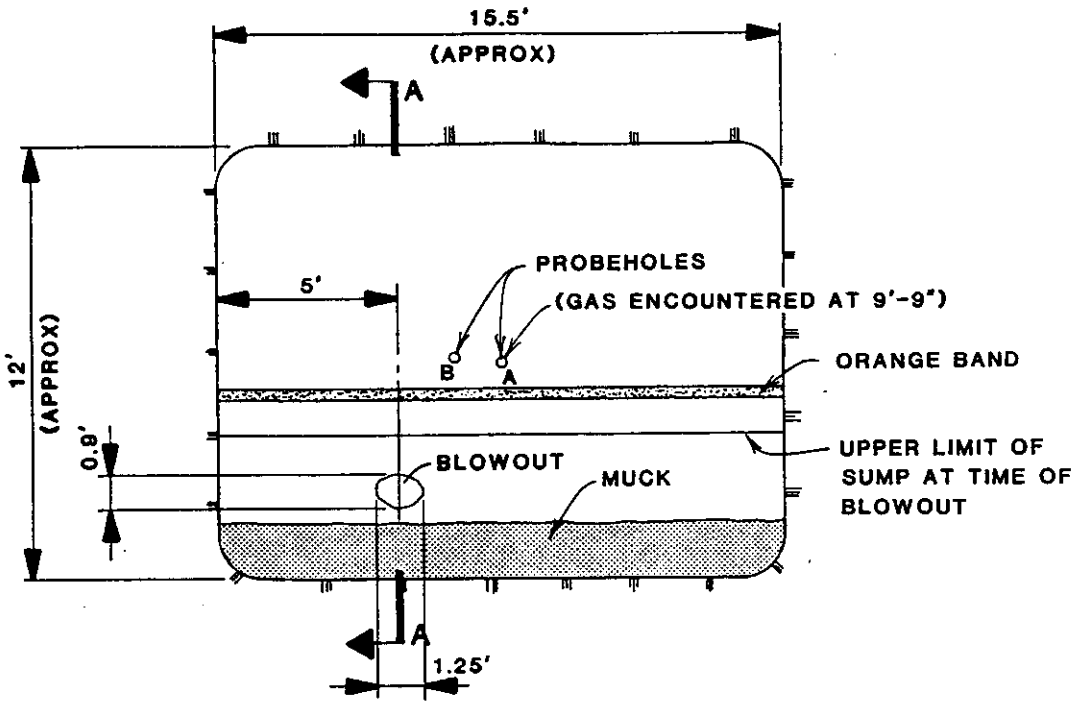
Description:

On Friday, March 21, 1986, at 1:00 p.m. the continuous miner was extending the S2180 drift to the east. While sumping the E233 face, a sudden exfoliation occurred, accompanied by the release of a small quantity of gas. A small slab of rock was thrown into the cutting head of the continuous miner. The miner operators reported hearing a sharp noise which was described as sounding like a shotgun discharge. All personnel were immediately evacuated from the area. All equipment, except the face fan, was shut off, and all appropriate safety and notification procedures were followed. A test was conducted for the presence of CH_4, NO_2, CO, H_2S, and SO_2, none of which were detected.

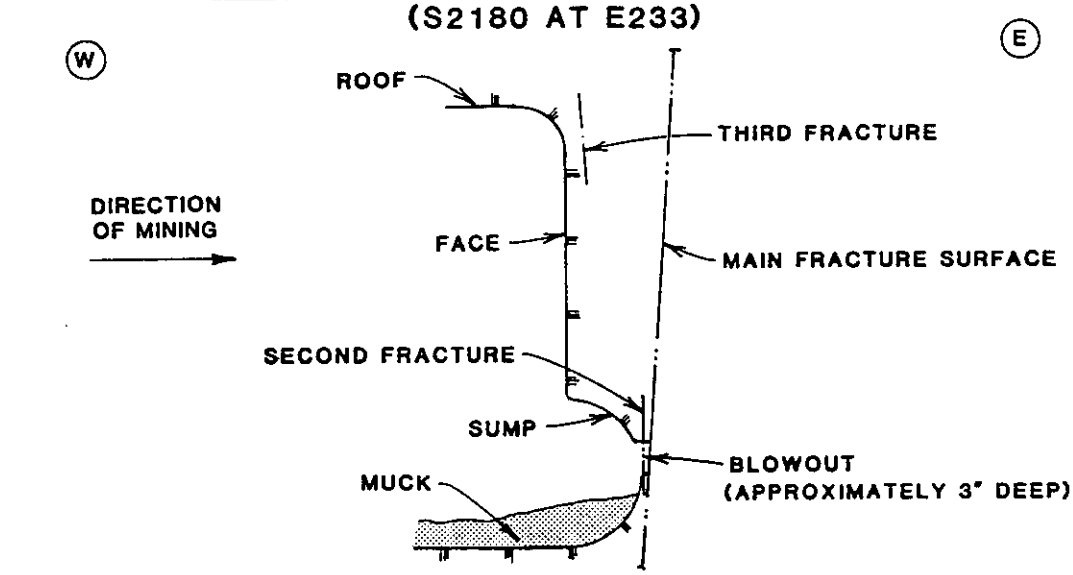
Inspection of the face showed that an oval-shaped slab of salt had exfoliated from the face. The slab was nearly vertical in orientation, 0.9 ft. high, 1.25 ft. long, and 0.25 ft. thick as shown in Figure C.1. The location was approximately 5 feet south of the north rib and 10 feet below the back. The source of the gas appeared to be two sub-parallel fractures oriented roughly north-south and dipping about 85 degrees to the west. The fractures were very clean, had no infilling, and no visible alteration of the surface. No brine was noted during the first examinations. However, on March 26, 1986, the day after mining, the main fractures stood out as a damp outline on the ribs, roof, and floor of the drift. The fractures appeared to be open 1/16 to 1/8 inch in the vicinity of the release, but mining showed them to be very tight away from the location of the gas release.

After mining was discontinued in the drift, mining operations proceeded to drill a horizontal probe hole close to the center of the face (Hole A, Figure C.1). At 5:00 p.m. the same afternoon, when the drill had penetrated to a depth of 9.75 feet, another fracture containing gas was encountered. The drill and 10 feet of drill steel were ejected from the hole accompanied by a brief noise like "a broken air hose." The area was again evacuated and another test was conducted for the presence of H_2S and SO_2 gas, neither of which were detected. Mining operations were suspended over the weekend. A second horizontal probe hole was drilled on Monday, March 24th, parallel to and about 2 feet north of the first hole, to a depth of 60 feet (Hole B, Figure C.1). No additional gas was noted.

Upon resumption of mining in the drift on March 25th, geotechnical personnel monitored the face advance to describe the fractures and any additional gas occurrences. As the face above the location of the exfoliation was mined, an additional gas release was observed. There was a visible "puff" of dust from the upper north corner of the face above and to the west of the exfoliation site. The continuous miner was shut down immediately, but no additional indications of a gas release were noted. This release came from a fracture which



VIEW LOOKING EAST AT WORKING FACE
(S2180 AT E233)



SECTION "A-A"

Figure C.1

Location of Gas Releases at the Working Face
at S2180 and E233

had a similar orientation to the fractures involved in the exfoliation and may have been part of the same fracture system. The fracture was very tight and had no evidence of infilling. However, a small and unmeasurable amount of brine and gas bubbles issued from this fracture. This fracture was not traceable once the area had been mined. The smell of "rotten vegetables" was reported in both of these cases of gas release.

As the mining face was advanced close to the point where the first probe hole encountered gas (9.75 ft.), excavation was carefully monitored. The source of the gas at that location was another near-vertical north-south trending fracture (Figure C.2). This fracture was very tight, hard to see, and not distinguishable in the roof or ribs after the area was mined. Continued mining eastward along S2180 exposed three additional fractures in the upper portion of the face with north-south trends and dips of about 50 degrees east (Figure C.2). It is not known whether these fractures are related to the gas-containing fracture encountered in the first probe hole or not. The fractures in the back have a much shallower dip, and there was no visible evidence of gas.

Careful monitoring of the mining continued, and other very minor, gas releases were noted. Most of the occurrences were in the form of small "weeps" of bubbling brine not associated with any recognizable fracturing, and generally not lasting more than 10 or 15 minutes. At S2180/E255, an audible hiss was noticed at the face. The hiss was only noticed after the continuous miner was shut down for lunch break. It was audible for about seven minutes, and minor amounts of brine and gas bubbles were still seeping from a fracture when mining resumed 20 minutes later. The fracture associated with this release was not as obvious or as well developed as the previous fractures.

In all of the cases listed, the "rotten vegetable" smell was present in various intensities. The odor was also often noted when approaching the face immediately after an area was mined.

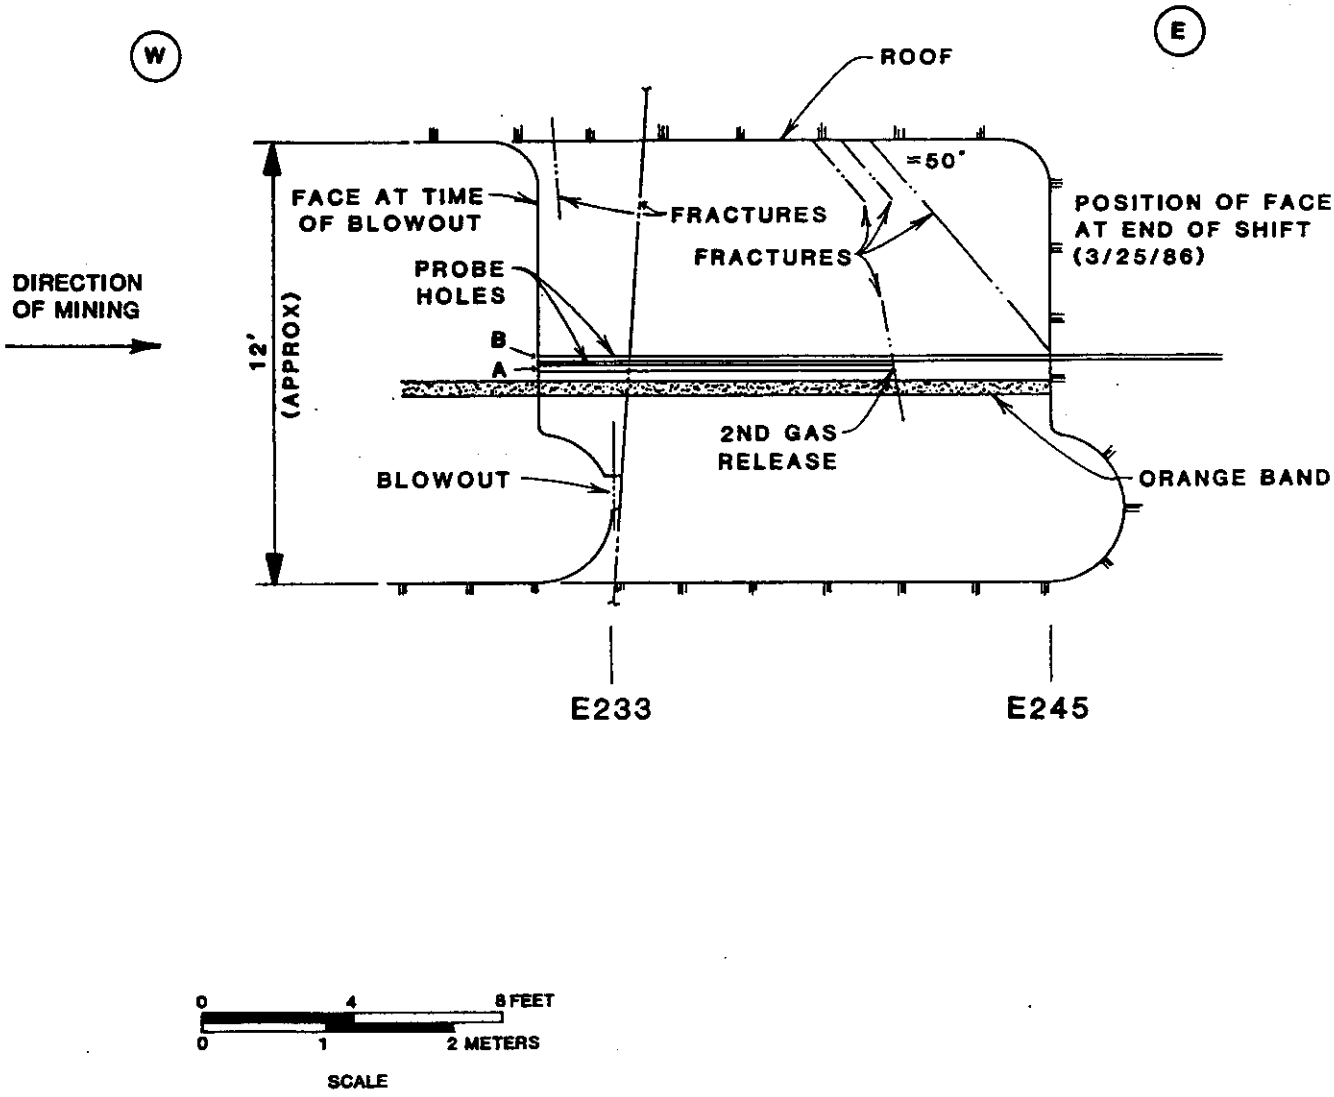


Figure C.2

Cross Section of the S2180 Drift
in the Vicinity of E233

REPORT OF GAS OCCURRENCE

Location: Intersection of S1950 and E300

Date: 3:00 p.m. on Monday, April 7, 1986

Description:

Gas was heard blowing from the vertical pressure release hole drilled into the back at the intersection of S1950 and E300 when the continuous miner was shut down at the end of the shift. Safety was notified and they ran tests for the presence of CH_4, CO, H_2S, NO_2, CO_2, and SO_2, none of which were detected. In addition, they reported being able to feel gas coming from the hole when a hand was placed at the opening and smelling a slight "rotten cabbage" odor. The mining face at the time of the gas release was at about S2090 in the E300 drift. The hole was not blowing when checked at 10:00 a.m. on Tuesday.

REPORT OF GAS OCCURRENCE

Location: E300 Drift at S2140

Date: April 9, 1986

Description:

On Wednesday, April 9, 1986, at about 10:00 a.m., there was a small gas release at S2140 in the E300 drift. A roughly oval-shaped piece of salt was rapidly exfoliated from the working face, accompanied by a small pop. Debris was thrown about 20 feet. This exfoliation left an elongate hole in the salt 2 ft. high, 0.6 ft. wide, and 0.0 to 0.2 ft. deep, increasing in depth from west to east. The release was located in the upper east corner of the face, about 1 foot below the back and 1 foot west of the east rib. The cutting head of the miner was sumping in the lower west corner of the face when the gas release occurred.

There was an obvious fracture at the back of the space left by the exfoliating slab of salt. The fracture was oriented N50E and dipped 53 degrees south. The fracture was open as much as 3/8 inch in the area of the cavity, but was very tight away from that immediate vicinity and disappeared entirely in the clayey zone below. The open part was in the clear halite and no evidence showed infilling or alteration of the surfaces to indicate whether or not there was a cavity there prior to mining.

Tests were conducted to detect the presence of H_2S, SO_2, NO_2, and CH_4, none of which were detected.

Another minor gas occurrence was noted in the E300 drift at about S1960 on April 2 at about 11.30 a.m. The mining machine had been cutting to the south and was shut down for lunch. An audible hiss was noted coming form the horizontal probe hole which had been drilled ahead of the face to the S2180/E300 intersection about a week earlier. No gas releases had been noted during drilling. The intensity of the hiss decreased gradually with time, but continued for at least 50 minutes and was still audible just before the miner started up after lunch.

APPENDIX D

PHASE I PRELIMINARY SAMPLING AND EVALUATION OF BRINE OCCURRENCES AT THE WIPP REPOSITORY HORIZON

This appendix contains a discussion of the Task 2 sampling activities that were part of Phase I of the WIPP Brine Sampling and Evaluation Program (BSEP). Included in this discussion is a description of sampling methodology, the manner in which the data was handled and calculations made, and a location-by-location description of both the sampling and the sampling results. The data obtained during Task 2 of Phase I are presented in tabular form in Appendix E.

1.0 SAMPLING METHODOLOGY AND PROBLEMS

The general procedure for brine collection and inflow measurements was simply to provide for the accumulation of the small brine inflows, to collect those accumulations on a periodic basis (approximately once a week for initial collections), and to measure the volume that had accumulated since the previous sampling. These measurements were then recorded and tabulated as the average fractions of liters per day collected from each location.

A variety of field techniques were used, depending upon the specifics of each occurrence. They can be broken down into the following groups:

- Initial volume measurements, experimental pumping techniques, and water-level measurements
- Vacuum-assisted sampling probe for brine removal from downholes
- Hand-operated rotary suction pump
- Continuous, gravity-driven collecting installations
- Pressure-vacuum and vacuum moisture-sampler installations

Additional details concerning the brine sampling procedures is provided in WIPP Procedure WP 07-410.

Down-hole sampling was done with a variety of bailing devices, most of which relied on check valves to retain collected brine while the bailer was raised to the surface (the floor of the repository workings). These devices occasionally failed when debris (mostly salt crystals and other muck in the holes) prevented the valves from seating properly, allowing some brine to leak from the sampler and flow down the inside of the drill hole. The result was an anomalously small recorded value for brine withdrawn at that time, usually followed the next week by a larger than expected amount. In most cases, the average of those two values was consistent with the trend of earlier and later readings. The result is a "kick" in the data that is not representative of the actual, much more consistent, inflow rates. Such sampling problems were noted on the field data sheets.

The bailing techniques would remove most, but not all of the brine in the hole. The amount of brine remaining in the hole was a fairly consistent amount, so the values obtained for "brine removed" were very close to the amount that actually flowed into the hole during the period between evacuations. After sampling, a visual inspection was made of the bottom of the hole to see if the bottom was at least partially exposed. If a partially-dry bottom was not observed after initial evacuation, the sampler was lowered to the bottom again and the evacuation repeated. After bailing, the downholes were plugged just below the collar with a piece of plastic foam which was covered, in turn, by a metal lid. The plug and lid prevented the inadvertent introduction of foreign solids into the hole and reduced moisture loss by evaporation to the repository atmosphere.

Evaporation has played a significant role in reducing the measured amounts of brine inflow, especially from the upholes. Several techniques were used to seal the collar of the upholes, but none of the techniques completely controlled evaporation. The projected high temperatures that will eventually be reached in Rooms A1, A2, A3, and B required that some of the materials used in the initial phases of the study be removed (they might give off deleterious vapors at high temperatures) and caused the replacement of some plastic items with metal.

Occasionally large "kicks" are observed in the uphole data. Many of these are a result of the clearing of a temporary blockage in the plastic tube leading from the collecting device at the hole collar to the collecting container. It was not uncommon for pieces of clay to slough from the clay seams exposed in the holes and for clay to fall down into the collecting device. The clay, in addition to pieces of salt that either fall from the sides of the hole or accumulate by the evaporation of brine, occasionally completely plugged the devices.

The result of these conditions and disruptions are that the data from the upholes should be considered as providing only minimum inflow data. Additionally, the effects of heat, the presence of metal, and the close proximity of many other holes need to be considered when evaluating the data from the A rooms and Room B.

2.0 DATA HANDLING AND CALCULATIONS

The data collected as part of the BSEP were initially recorded on field data sheets and then transferred to a computerized data base using an IBM XT microcomputer. Standard software programs (dBase III Plus and Lotus 1-2-3) were used for storage and calculations. Samples were collected about once a week except for special circumstances discussed later. The amount of brine removed was measured to the nearest hundredth of a liter and recorded, along with the date and time of collection, on the field data sheets. Brine levels were also measured and recorded. An approximation of the volume of brine in the downholes can be calculated from the height of the column of brine in the hole and the average diameter of the hole. The result of this calculation is less accurate than actually measuring the volume of brine removed, but the brine level was routinely measured prior to attempting evacuation of the accumulated brine. In a few instances, the brine level data were used to resolve apparent anomalies in the brine volume measurements that resulted from equipment failure or human error.

The dates and times at which collections were made were transformed into decimal days since an arbitrary reference date (January 1, 1985) and the elapsed time in decimal days between samples was used to calculate average brine inflow rates in terms of fractions of liters per day.

As described in Section 1.0, much of the variability in the quantity of brine collected resulted from limitations of the collecting techniques rather than variations in the actual inflow of brine from the bedrock into the collecting locations. As a result, plotting of the inflow data from the data tables (Appendix E) results in an irregular plot which implies variations in inflow that, in fact, do not exist. The graphed data included in this report were processed and plotted by a standard computer software program (STSC Statgraphics) on an IBM AT microcomputer, using a simple moving average to smooth the curves. A five-point moving average was used for the majority of the graphs. The smoothed result reflects trends that are representative of the brine inflow rates while still showing variations that are probably the result of collecting problems.

An alternative technique to smooth the data is to plot cumulative inflow against time, fit a curve to that plot, and then differentiate the best-fit equation to determine the flow rate. This technique may be attempted after more data has been acquired.

3.0 OBSERVATIONS

3.1 Room 1, Hole IG202

SPDV Test Room 1 was one of the first rooms excavated in the northern part of the WIPP underground (Figure D-1). Initial mining was finished on April 13, 1983, and a number of instrument holes were drilled in it during the following few weeks. One of those was downhole IG202, located near the west rib in the center of the room, which was drilled for use as an inclinometer observation location. It is lined with a 74 millimeter (2 7/8th inch) I.D. flexible PVC inclinometer guide tube that is not a normal well casing. Leaks may occur into the guide tube. This type of liner has flexible expansion joints that can transmit fluids and a plastic cap on the bottom that was not installed with the intent of preventing brine inflow.

IG202 was drilled using brine as the drilling fluid. On April 21, 1983, the PVC guide tube was installed in the hole and a small-diameter tremie pipe (plastic tubing) was used to grout the liner in place. It is likely that the grouting is incomplete and that vertical movement of fluid takes place in open, ungrouted spaces outside the guide tube. When the guide tube was installed, it was filled with fresh water to assist in sinking the guide tube to the bottom of the hole. The fluid in the guide tube was reportedly blown out with compressed air, but it is not known how complete that removal was. It is probable at least some fluid remained in the partially grouted space outside the guide tube and in pore spaces and fractures in the rock which drained into the bottom of the hole after it was "blown dry."

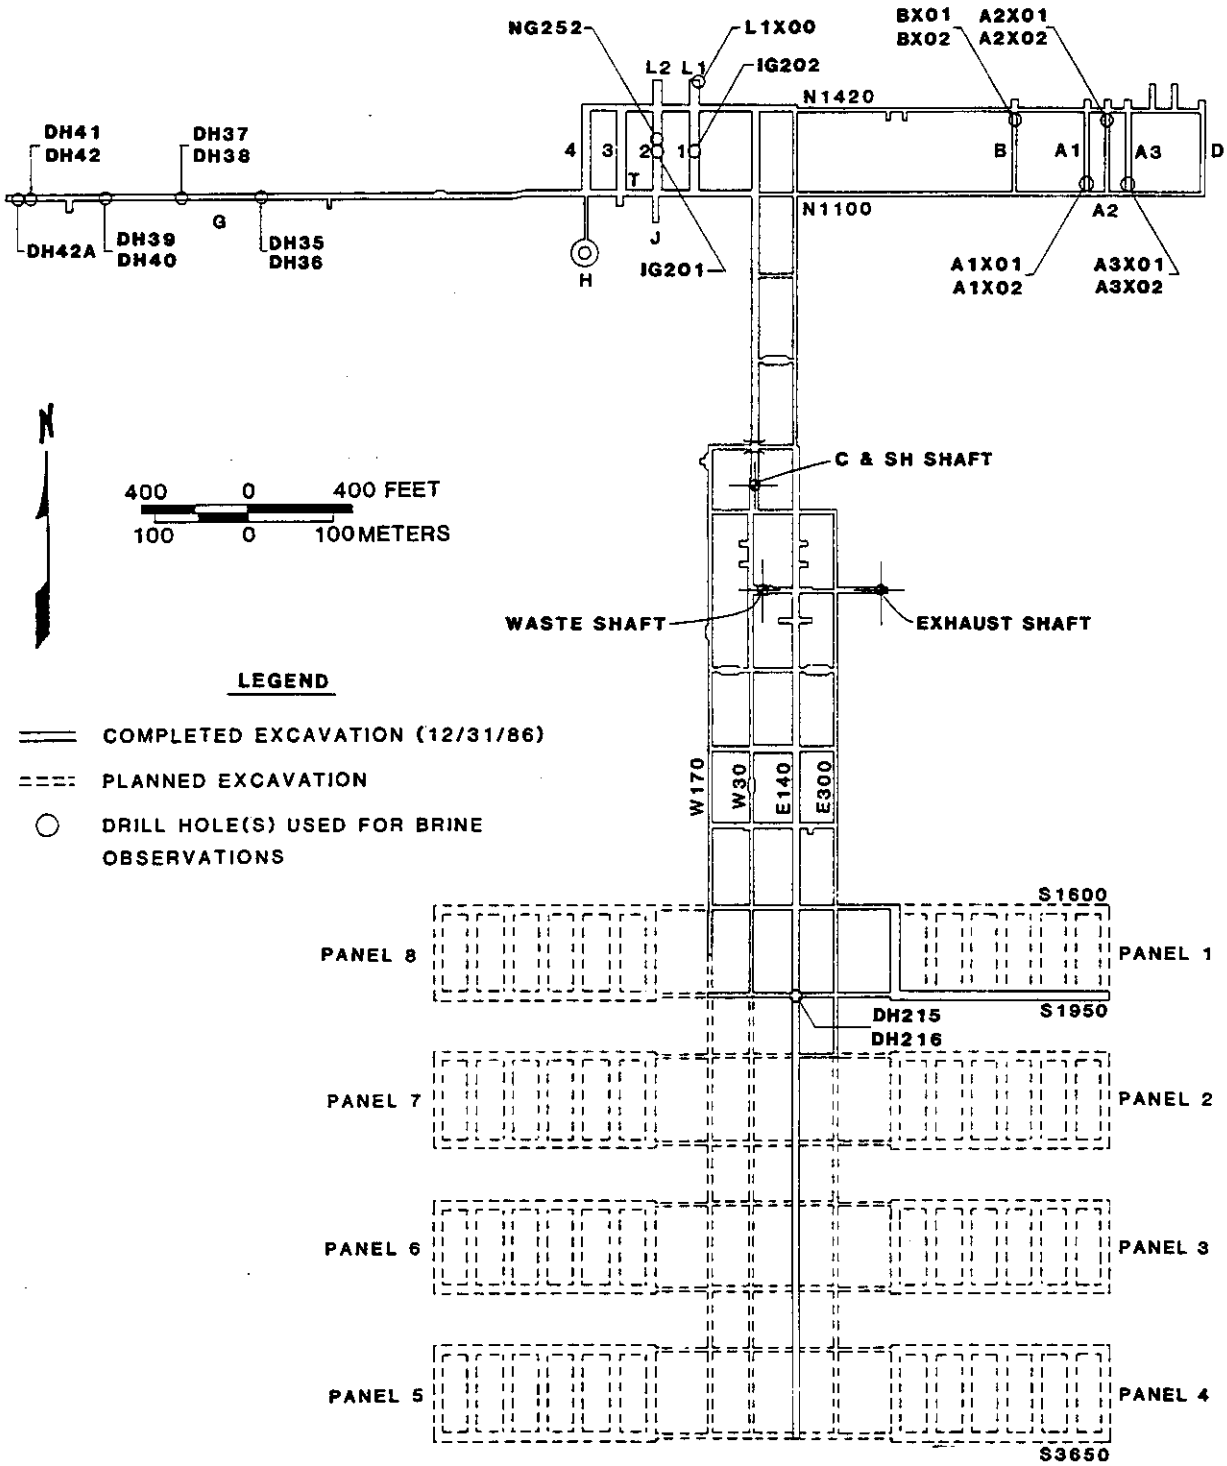

Figure D-1.

Map of the WIPP Underground Workings

On November 30, 1984, fluid filled the hole to within approximately two meters of the collar. It is known that fluids were introduced into this hole on at least two occasions (brine of unknown composition at the time of drilling and fresh water during guide-tube emplacement). The chemistry of fluids in this hole has certainly been affected by the materials and fluids introduced into the hole, especially the grout. Room 1 was also used by the mining contractor as an underground shop and lunchroom. As a result, the origin, quantity, and chemical composition of the fluid in the hole at the time of initial BSEP testing was probably not representative of naturally occurring, spontaneous inflows from the surrounding rocks.

This hole was the location of some of the initial experiments with air-jet pumping techniques. On November 30, 1984, over 52 liters of brine were removed from the hole and the inside of the guide tube was blown as dry as possible with high-pressure air. On January 8, 1985, an additional 12.6 liters was removed and the inside of the guide tube blown dry again. Some brine was lost during both of these evacuations, so those figures, although reasonably accurate, represent minimum figures for the amount of brine actually in the hole. Evacuation using the vacuum-assisted sampling system and measuring technique described in WIPP Procedure WP 07-410 began January 15, 1985, and continued until October 15, 1985, when the guide tube had become so distorted due to shear movement in the bedrock that sampling was discontinued for fear that the sampling device would become wedged in the hole. Most of the displacement is taking place along fractures in anhydrite interbed MB 139, which is about one to two meters below the floor of Room 2 (Figure D-2).

Relatively few data points exist for the inflow data for IG202. As a result, a four-point moving average was used to smooth this data (Figure D-3) instead of the five-point average used for most of the rest of the data.

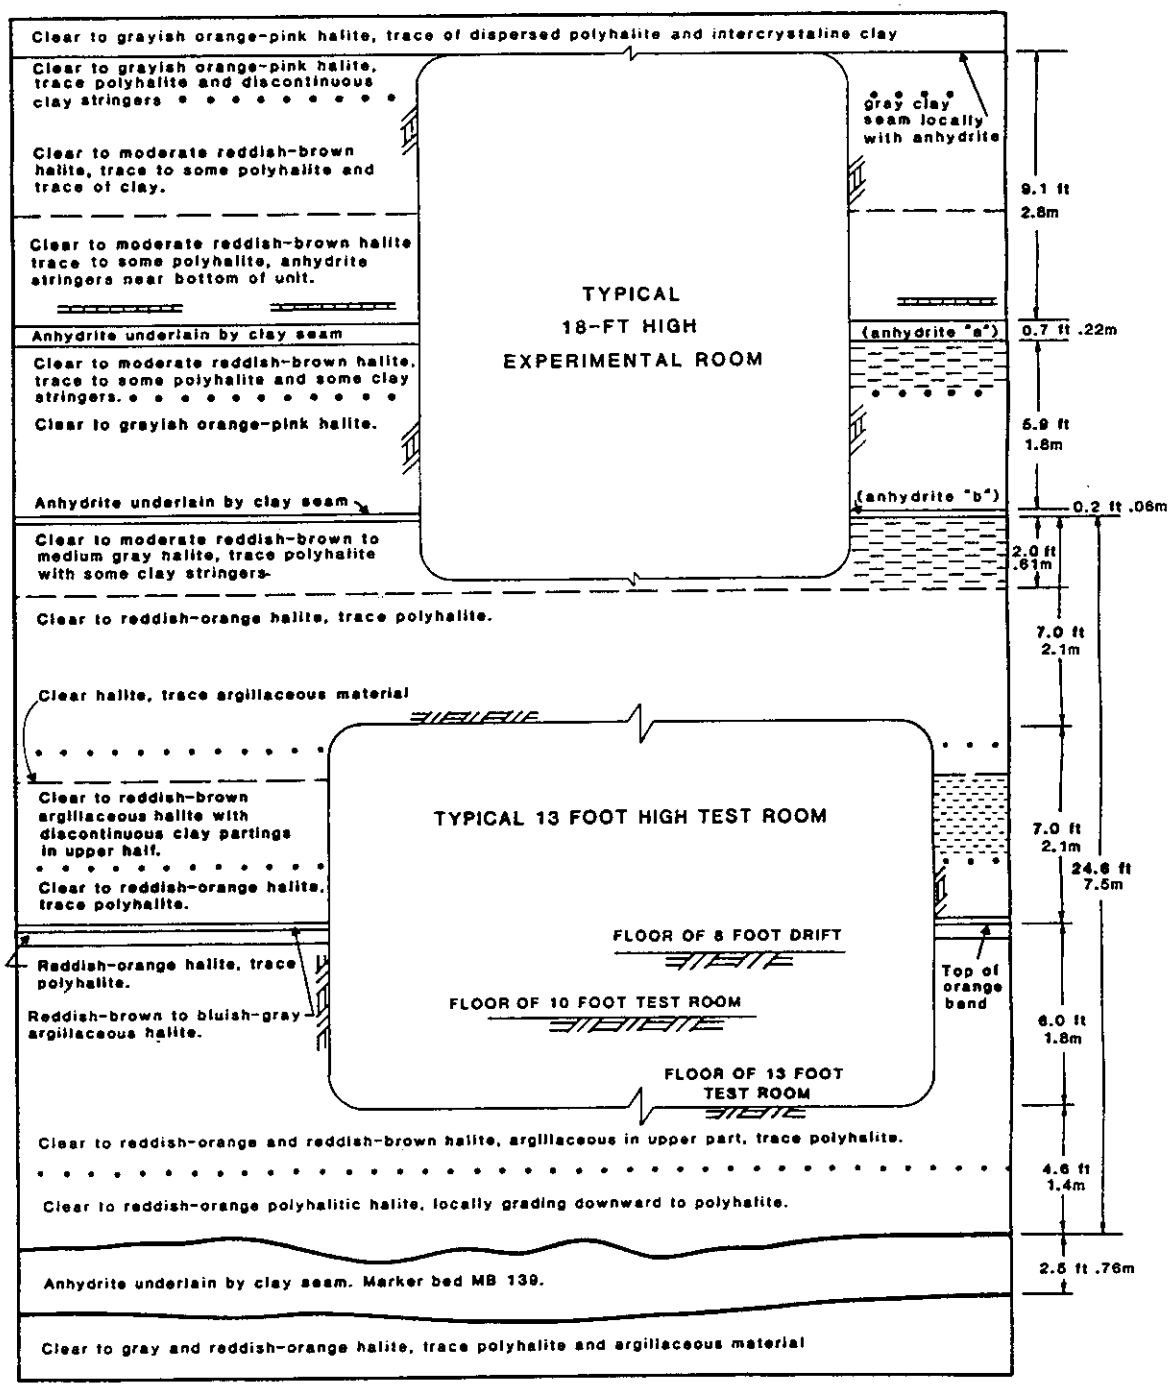
Average inflow rates were on the order of 0.05 liters per day in early 1985, decreasing gradually for about 175 days (Table E.18; Figure D-3). Inflow rates leveled out to between 0.01 and 0.02 liters per day for the remainder of the sampling period with the fluctuations falling within the limit of error of the sampling and measuring techniques. A total of over 71 liters of brine was removed from hole IG202 between November 30, 1984 and August 24, 1986.

3.2 Room 2

SPDV Test Room 2 was also one of the first rooms excavated in the northern part of the WIPP underground (Figure D-1). Initial mining was finished March 17, 1983 and a number of test holes were drilled in it during the following few weeks. Two of these holes were included in Phase I of the BSEP: inclinometer hole IG201 and stressmeter hole NG252.

3.2.1 Hole IG201

IG201 was drilled for use as an inclinometer observation location and is located near the west rib in the center of Room 2. Brine was used as the drilling fluid. On March 28, 1983 a 74 millimeter (2 7/8th inch) I.D. PVC guide tube identical to the one in Hole IG202 was installed in the hole, and a small-diameter tremie pipe (plastic tubing) was used to grout the liner in



NOTES:

1. Dimensions and lithologic descriptions are derived primarily from corehole and geologic mapping data from the four test rooms and experimental area supplemented by geologic information from the remaining SPDV excavation.
2. Unit thicknesses are approximate and vary slightly.
3. Room dimensions have changed with time due to salt-creep closure.

Figure D-2.

Geologic Cross Section of the Facility and Experimental Level

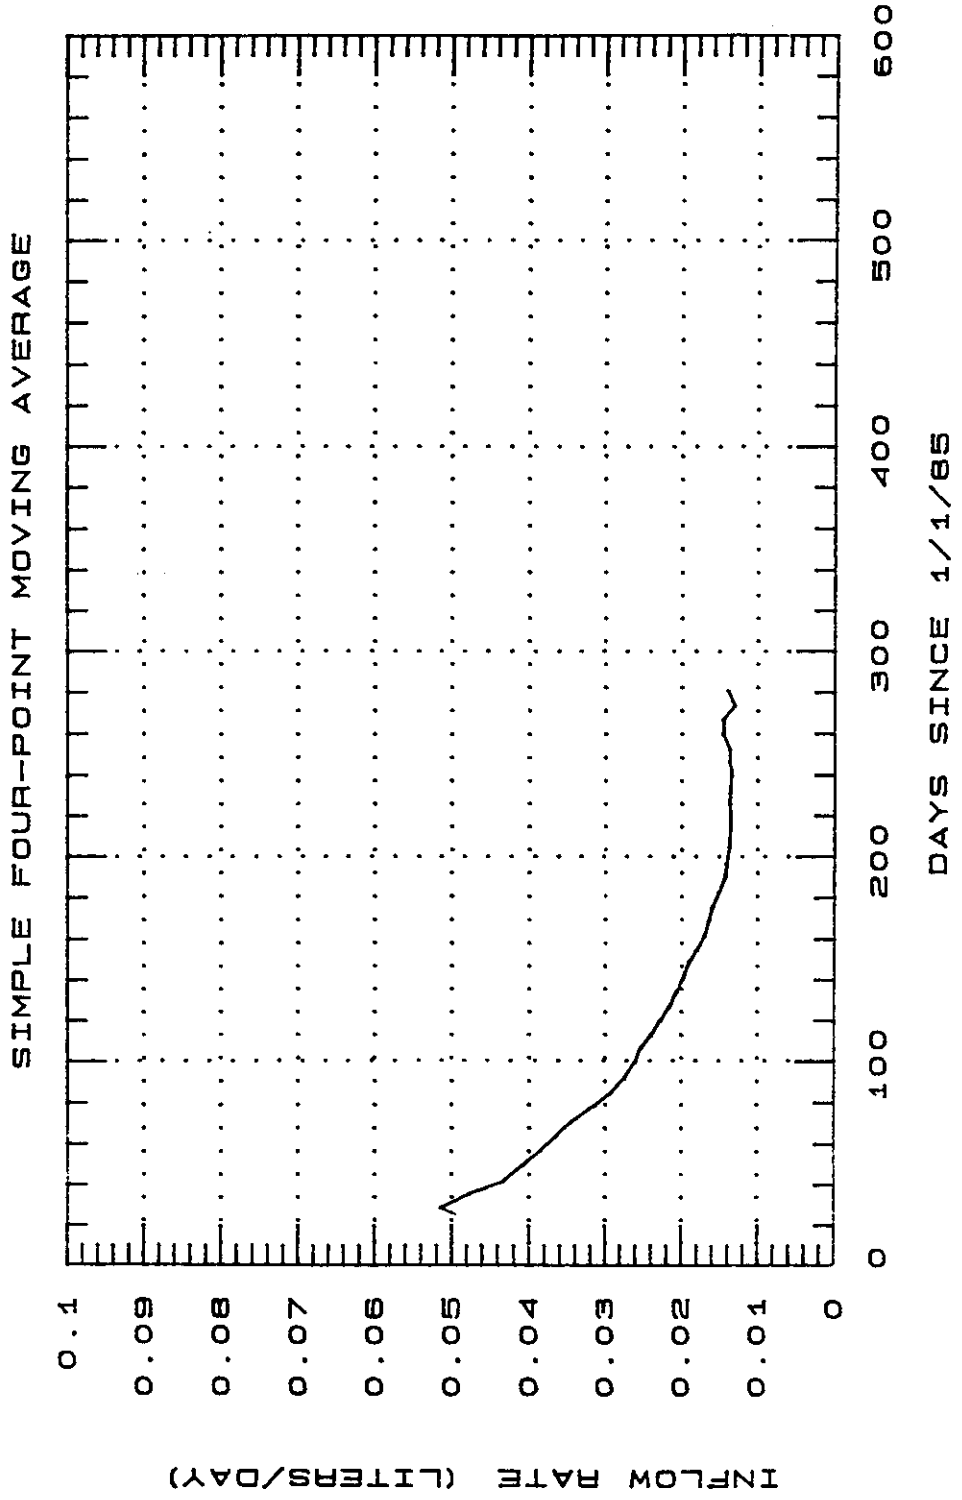


Figure D-3.
IG202 Inflow Rates

place. It is highly likely that the grouting is incomplete and that vertical movement of fluid takes place in open, ungrouted spaces outside the guide tube. When the guide tube was installed, it was filled with fresh water to assist in sinking the guide tube to the bottom of the hole.

On November 21, 1984 fluid filled the hole to within 1.23 meters (4.05 feet) of the collar. It is known that fluids were introduced into this hole on at least two occasions (brine of unknown composition at the time of drilling and fresh water during guide-tube emplacement). The chemistry of fluids in this hole has certainly been affected by the materials and fluids introduced into the hole, especially the grout. Room 2 was also used by the mining contractor as an underground storage area. The origin, quantity, and chemical composition of the fluid in the hole at the time of initial BSEP testing was probably not representative of naturally-occurring, spontaneous inflows from the surrounding rocks.

This hole was the location of some of the initial experiments with air-jet pumping techniques. On November 21, 1984, about 8.4 liters of brine had been removed from the hole when the experimental pumping system failed. On November 30, 1984, an additional 54.7 liters were removed and the inside of the guide tube was blown as dry as possible with high-pressure air. On January 8, 1985, 1.5 liters were removed before the check valve failed on a different experimental sampler. An additional 2.5 liters were removed on January 9, 1985. Some brine was lost during these evacuations, so those figures, although reasonably accurate, represent minimum figures for the amount of brine that was actually in the hole. Evacuation using the vacuum-assisted sampling system and measuring technique described in WIPP Procedure WP 07-410 began January 15, 1985.

Initial brine inflow rates were slightly greater than 0.05 liters per day, decreasing gradually to slightly less than 0.02 liters per day at the end of April, 1986 (Table E.17, Figure D-4). At that time, the guide tube had become so distorted from shear within the bedrock that sampling was discontinued. A total of over 81 liters of brine had been removed from hole IG201 over that period of time.

3.2.2 Hole NG252

Stressmeter downhole NG252 is located about 3 meters north of IG201 in SPDV Test Room 2. This hole has a fairly complicated history (Figure D-5). The initial 38 millimeters (1.5 inch) hole was drilled 2 meters (6.5 feet) deep in March 1983 with brine used as the drilling fluid. The stressmeter failed in December 1983 and on March 4, 1984, the instrument was over-cored with a 152-millimeter (6-inch) core barrel and removed. As a result, the upper 50 centimeters (1.5 feet) of this hole is 152 millimeters (6 inches) in diameter and the bottom 1.5 meters (5 feet) is 38 millimeters in diameter.

On November 21, 1984, this hole was found to be filled with both brine and muck. The top of the brine was 18 centimeters (7 inches) below the collar and the top of the salt muck was 28 centimeters below the collar. Approximately 1.3 liters of brine were removed on November 21, effectively evacuating the hole to the level of the top of the salt muck.

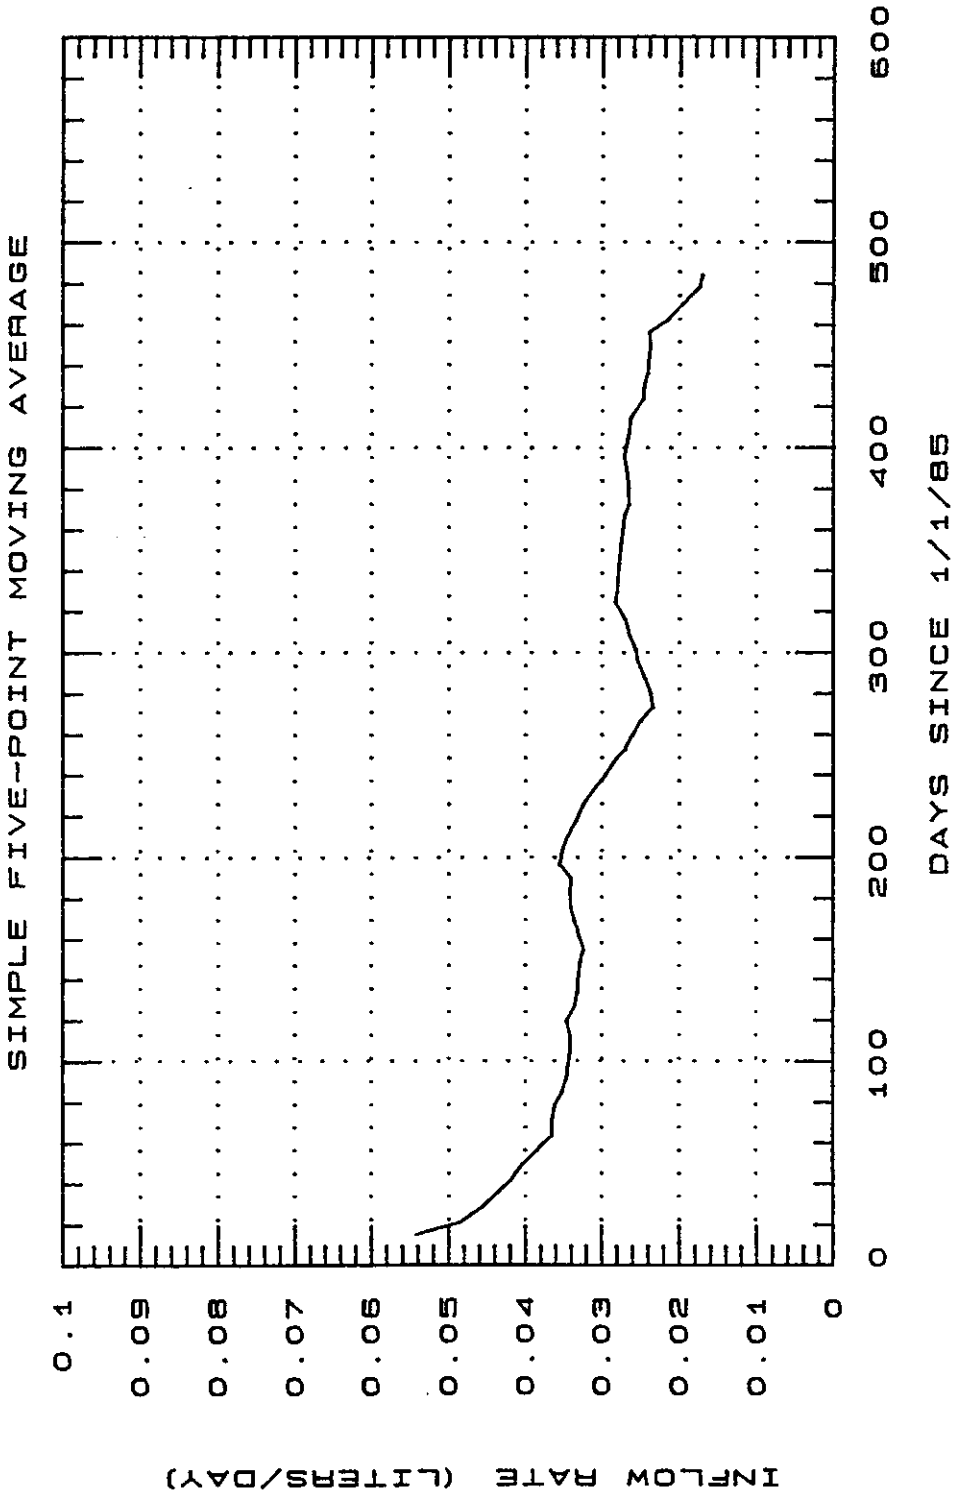

Figure D-4.
IG201 Inflow Rates

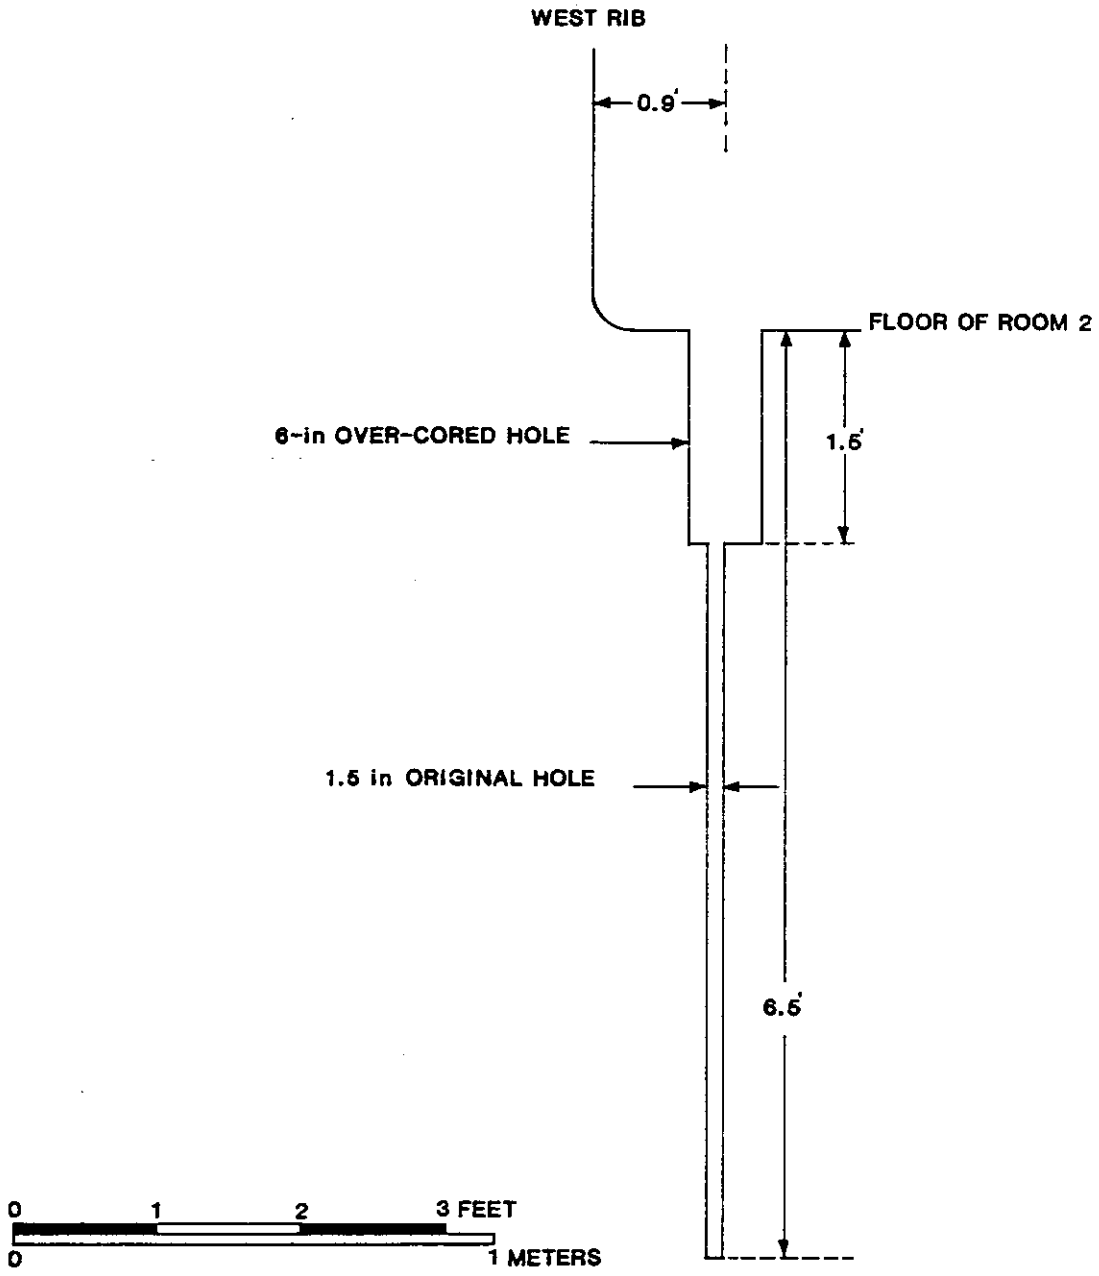

Figure D-5.
NG252 Configuration

Six days later, on November 27, 1984, the brine level had risen to 6.4 centimeters above the salt muck. About 0.76 liters of brine were evacuated, exposing the top of the salt muck. Later that day, the brine level was observed to have risen to completely cover the salt muck.

On November 29, 1984, compressed air was used to blow all the salt muck and accumulated brine out of NG252. The quantity of brine that was blown out was not measured, but it amounted to several liters. PVC casing with a cap was installed to prevent debris from entering and plugging the hole.

Twenty days later, on December 19, 1984, representatives of the Environmental Evaluation Group (EEG) collected a sample of brine from this location. On that date, the level of the brine surface had risen to approximately the level observed on November 21; 18 centimeters below the collar or about 50 centimeters below the top of the new PVC casing.

Since this hole was easily accessible, known to produce brine, and of small diameter, it was selected as the location for initial observations. The hole was evacuated and a short-term inflow test was performed following normal surface-well recovery analysis techniques. Initial brine levels were measured every hour. Intervals between measurements were lengthened as appropriate once initial inflow rates were determined. Measurements continued around the clock until the brine level stabilized (Table E.20).

The diameter of the hole enlarges from 38 to 152 millimeters at a point approximately 1.5 meters above the bottom of the hole. The inflow data was recorded as the increasing level of brine in the hole with time. To correct for the change in hole diameter, brine level was converted to approximate volume of brine in the hole by multiplying by the appropriate cross-sectional area. The calculations were made using Lotus 123 software. This figure is reported as equivalent volume in liters in Table E-20 and on Figures D-6 and D-7.

The data for the rise in static level was plotted both as an X-Y plot (Figure D-6) and as a semi-log plot (Figure D-7), the more conventional form for recovery graphs. These curves are not strictly analogous to "recovery tests," however, since the initial point for the curves probably does not represent a steady-state drawn-down condition. In addition, the distribution of potential energy (hydrologic regime) of the brine in the vicinity of the underground drill holes is still poorly understood.

Brine flowed into the evacuated hole from the fractures and pores close to the hole and, for a while, the hole actually filled faster the fuller it became. This can be seen on Figure D-6 between approximately 35 and 175 hours. Both graphs show an abrupt change-in-slope at a brine level of approximately 1.5 liters, where the hole diameter enlarged from 38 to 152 millimeters. Inflow ceased after the hole became filled with brine to a depth of approximately 6.1 feet. The floor of Room 2 slopes down toward the south, and it is probable that when Hole NG252 is filled to this level, additional inflow ceases because the brine discharges through some undetermined flow path into unconsolidated muck on the floor of Room 2. The conclusion reached was that this type of data, although interesting, is not very useful unless an equilibrium draw-down state is established prior to recording the rising brine level.

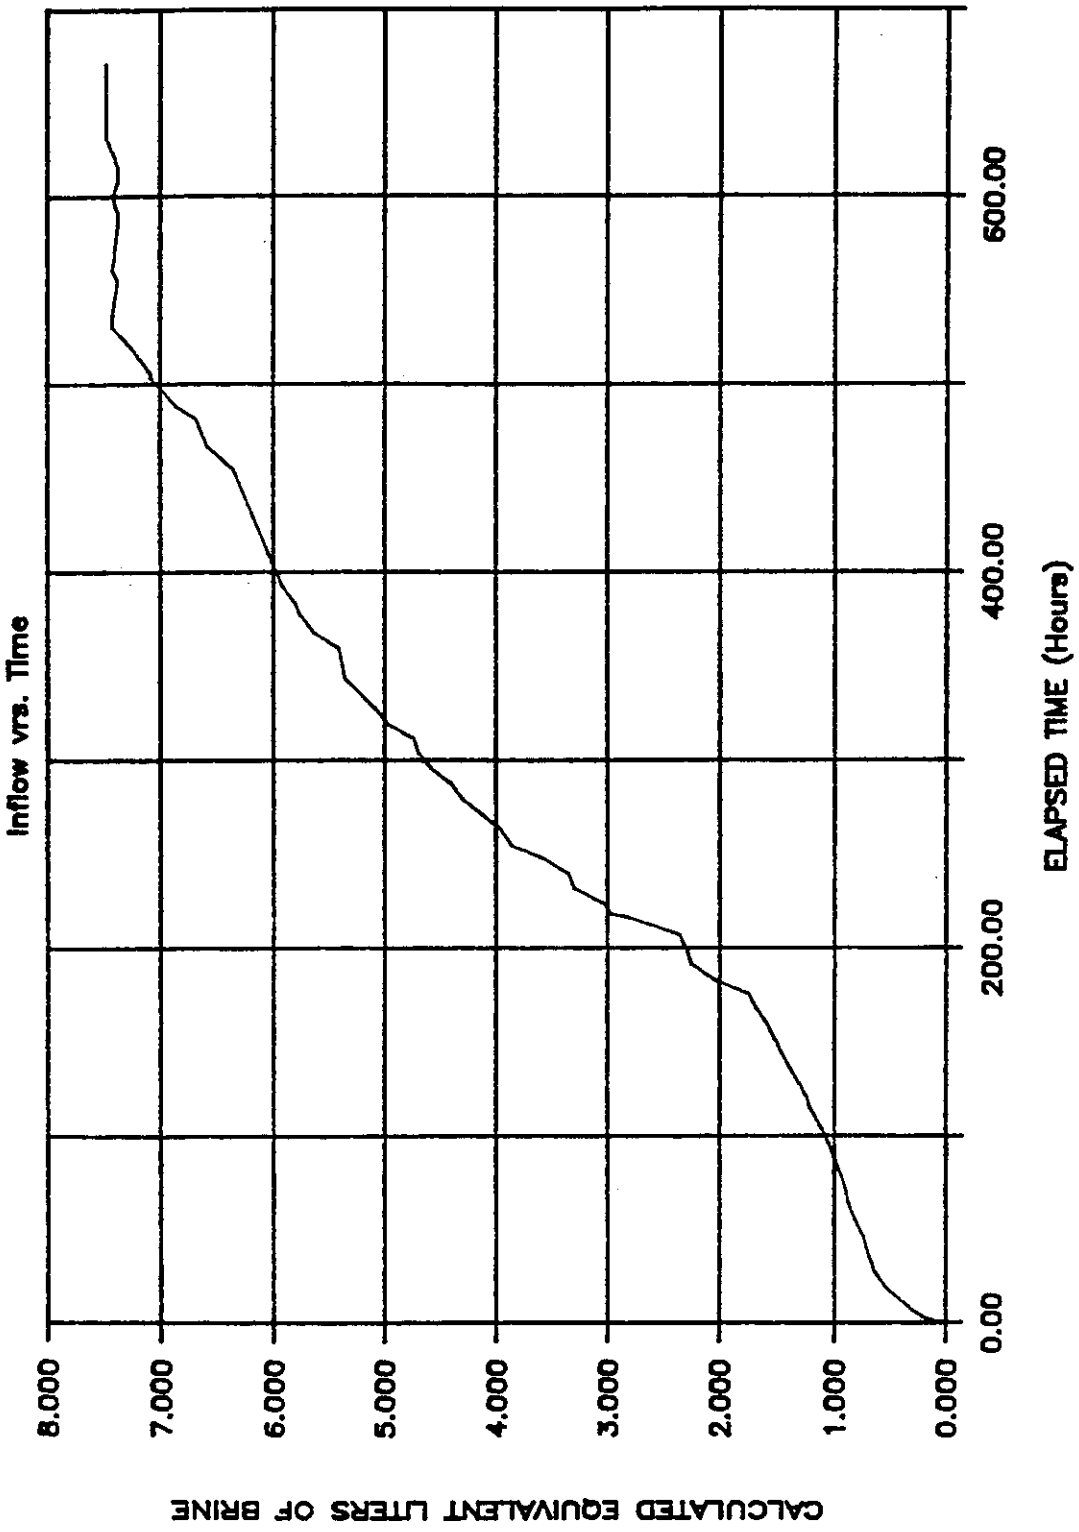

Figure D-6.

NG252 Short Term Inflow

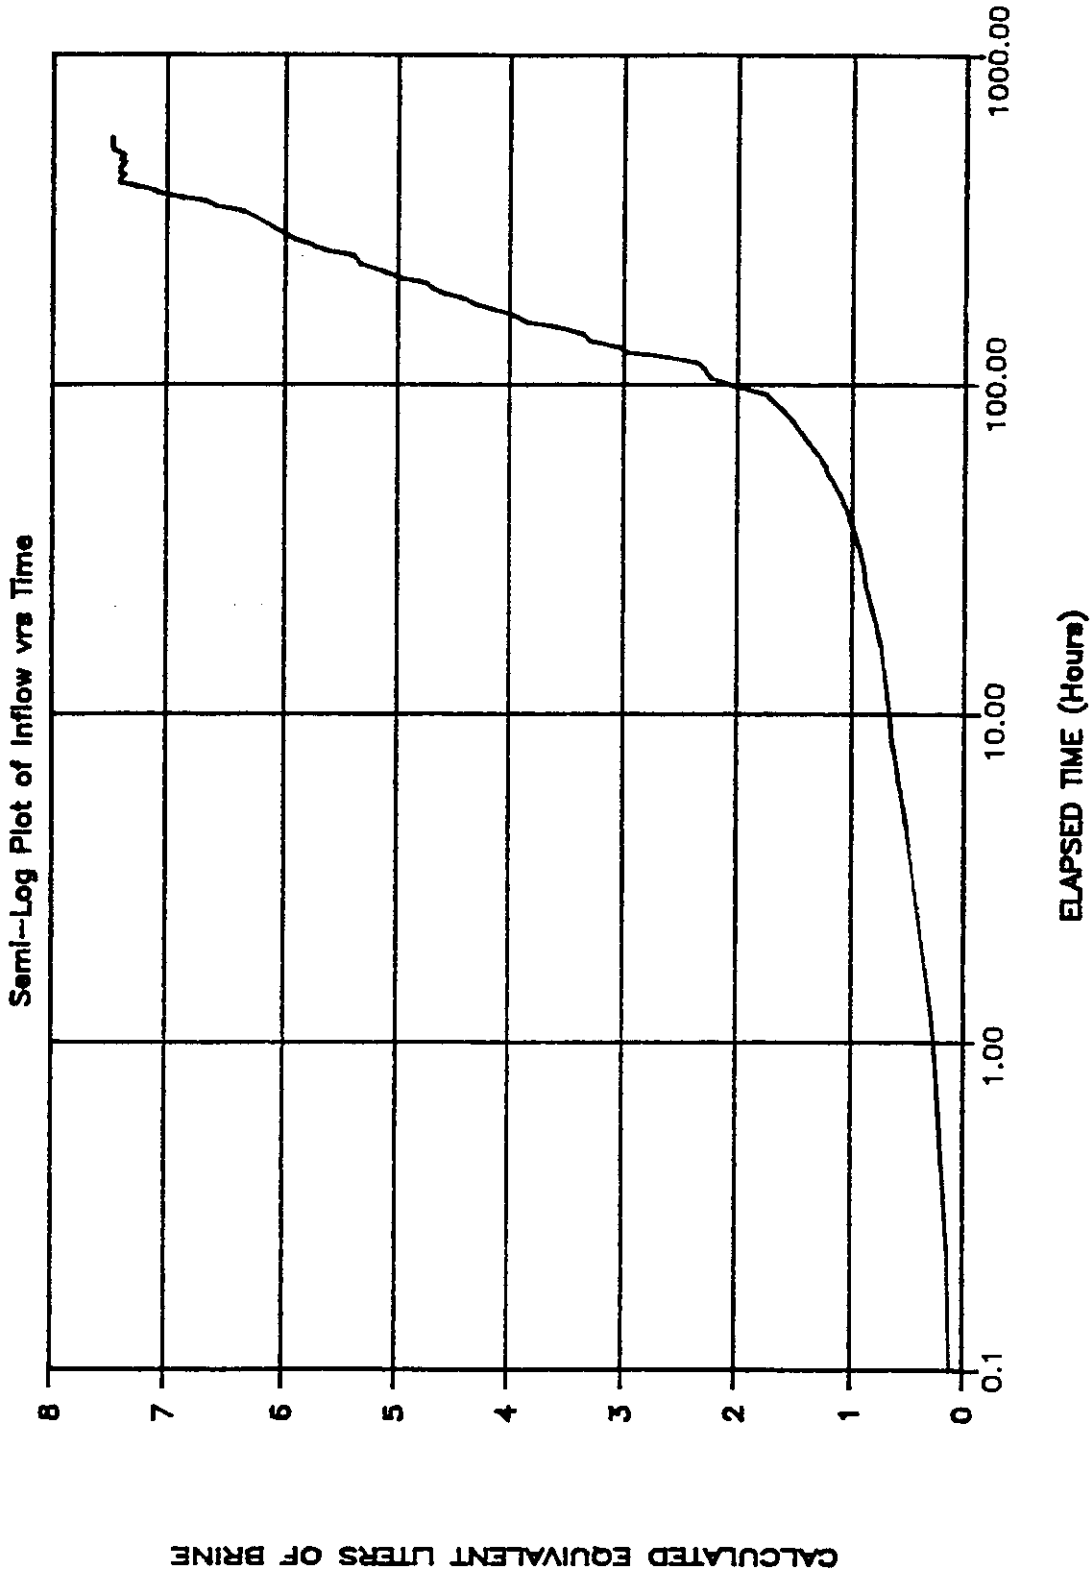

Figure D-7.

Semi-Log Plot of NG252 Short Term Inflow

Starting in February 1985, brine was bailed from NG252 on a regular basis (Table E.21; Figure D-8). Inflow rates were initially close to 0.6 liters per day, gradually declining to about 0.27 liters per day by August 19, 1986. Over 235 liters of brine had been removed from this hole by that date. Significant quantities of gas are associated with the brine inflow into NG252. Gas bubbles are almost always observed. Brine withdrawn from the hole effervesces immediately after bailing as it is poured from one container into another. NG252 penetrates anhydrite Marker Bed 139 and most of the brine flows into this hole from a fracture very close to the bottom of the hole, near the base of Marker Bed 139 (Figure D-2).

NG252 is the largest brine producer of any of the drill holes observed during Phase I of the BSEP, and appears to be something of an anomaly. It is located in close proximity to a completely dry downhole. The dry hole is approximately 4.7 meters east of NG252 on the centerline of Room 2, is 15 centimeters in diameter, is 1.65 meters deep, and penetrates into MB 139. It does not appear to completely penetrate MB 139, which may be the reason it is dry.

3.3 Experimental Rooms A1, A2, A3, and B

Experimental Rooms A1, A2, A3, and B are in the northeastern part of the WIPP underground workings (Figure D-1). Excavation of Room A1 was completed in October 1984, Room A2 in July 1984, Room A3 in November 1984, and Room B in June 1984. They are 5.5 meters (18 feet) high and are excavated in a zone about 6 meters (20 feet) stratigraphically higher than the rest of the workings (Figure D-2). As a result, the drill holes penetrate a slightly different stratigraphy, a fact that results in especially useful data. The end of 15-meter upholes typically penetrate rocks about seven meters stratigraphically above the end of other 15-meter upholes. Hole A1X02 is 18 meters long and penetrates an additional 3 meters, intersecting an anhydrite interbed not present in the other three upholes in Rooms A2, A3, and B. Downholes typically penetrate MB139 at depths of 7 to 7.6 meters. The data from these holes reflects both the sampling of different geological horizons and, perhaps, more importantly, interbeds such as MB 139 under different stress conditions than is encountered elsewhere in the facility.

These rooms all contain many experimental and instrument holes (Appendix A), almost all of which are inaccessible to the BSEP. In early 1985, a pair of stratigraphic observation holes were drilled in each of these rooms. These holes were drilled with air as the drilling fluid. Inflow to these pairs of holes have been monitored from the time they were drilled.

The A and B rooms are the location of the heated room experiments. Canisters containing electric heaters have been emplaced at the stratigraphic level of the facility, below the floor of the rooms. The power was turned on to the heaters in the A rooms on October 2, 1985 (day 274 after 1/01/85), and in Room B on April 23, 1985 (day 112 after 1/01/85). Since that time the rooms have been heating up, a factor that is expected to effect both the inflow of brine and the brine chemistry.

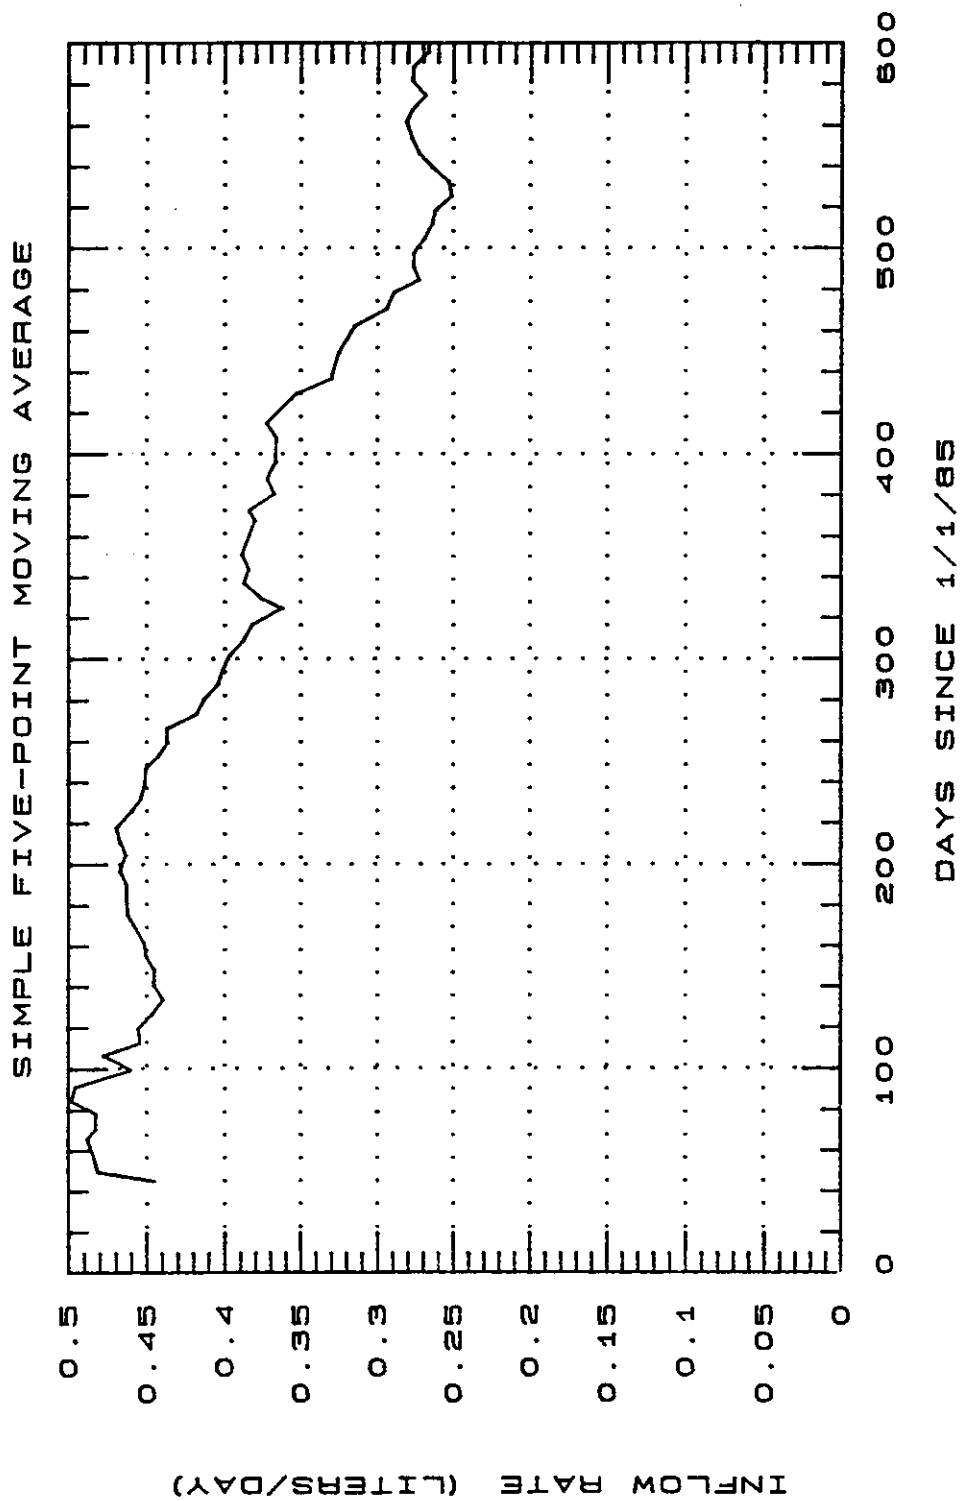

Figure D-8.

NG252 Inflow Rates

3.3.1 Room A1, Hole A1X01

Hole A1X01 is a downhole drilled in the south end of Room A1 on February 26, 1985. No brine or gas was noticed during drilling. Brine accumulations were noticed shortly after drilling. Brine was first removed from this hole on March 12, 1985. Inflow rates in April 1985, were on the order of 0.047 liters per day, gradually decreasing to slightly greater than 0.026 liters per day in October 1985. Inflow appeared to stabilized at that rate and remained quite constant through August 1986 (Table E.1, Figure D-9). A total of approximately 15.3 liters of brine had been removed from A1X01 by August 19, 1986.

3.3.2 Room A1, Hole A1X02

Hole A1X02 is an uphole completed March 7, 1985, in the south end of Room A1, directly over hole A1X01. The end of this hole penetrates beds that are stratigraphically higher than those penetrated by any of the other holes monitored as part of the BSEP, intersecting an additional anhydrite interbed. Drillers noted that brine entered the hole at a depth of 3.55 meters. The hole was reamed on February 28, 1985 to a 12.7 centimeters (5-inch) diameter for the first 3.7 meters to eliminate drilling problems caused by moist cuttings. A moist area was noted developing around the collar on March 7, 1985. On March 12, 1985 the moist area on the back (roof) extended for a third of a meter in all directions from the drill hole.

Several different types of collecting devices were installed, with successful collection of brine first occurring on April 2, 1985. Most of the irregularities in the data (Table E.2) are a result of collecting difficulties and evaporation losses, not real variations in brine inflow. Inflow rates were on the order of 0.02 liters per day between drilling and the end of October 1985, decreasing slightly between November 1985 through June 1986, followed by an increase to almost 0.04 liters per day in August 1986 (Figure D-10). A total of over 8.7 liters of brine had been collected from this hole by August 19, 1986. A significant, additional amount was certainly produced from the hole but lost by dissipation near the borehole collar and evaporation to the repository atmosphere.

3.3.3 Room A2, Hole A2X01

Hole A2X01 is a downhole completed February 9, 1985 in the north end of Room A2. No brine or gas inflows were noted during drilling, but moist, irregular vugs were observed in the core, usually in coarsely crystalline polyhalitic halite, clear halite, and halite containing some brown clay. Brine accumulations were noticed shortly after drilling. Brine-soaked muck containing some oil (contamination from the drilling operations) was first removed from this hole on February 19, 1985. Mixtures of brine and muck were also bailed from the hole on March 7, 1985 and March 12, 1985. On March 20, 1985, 0.52 liters of fairly clear brine were removed from the hole (Table E.3). Initial inflow rates in late March and early April 1985, were slightly greater than 0.05 liters per day, declining fairly rapidly to slightly less than 0.035 liters per day by mid-May. Inflow then remained quite steady, decreasing very gradually to about 0.025 liters per day in late August 1986 (Table E.3, Figure D-11). A total of approximately 16.8 liters of brine had been removed from A2X01 by August 19, 1986.

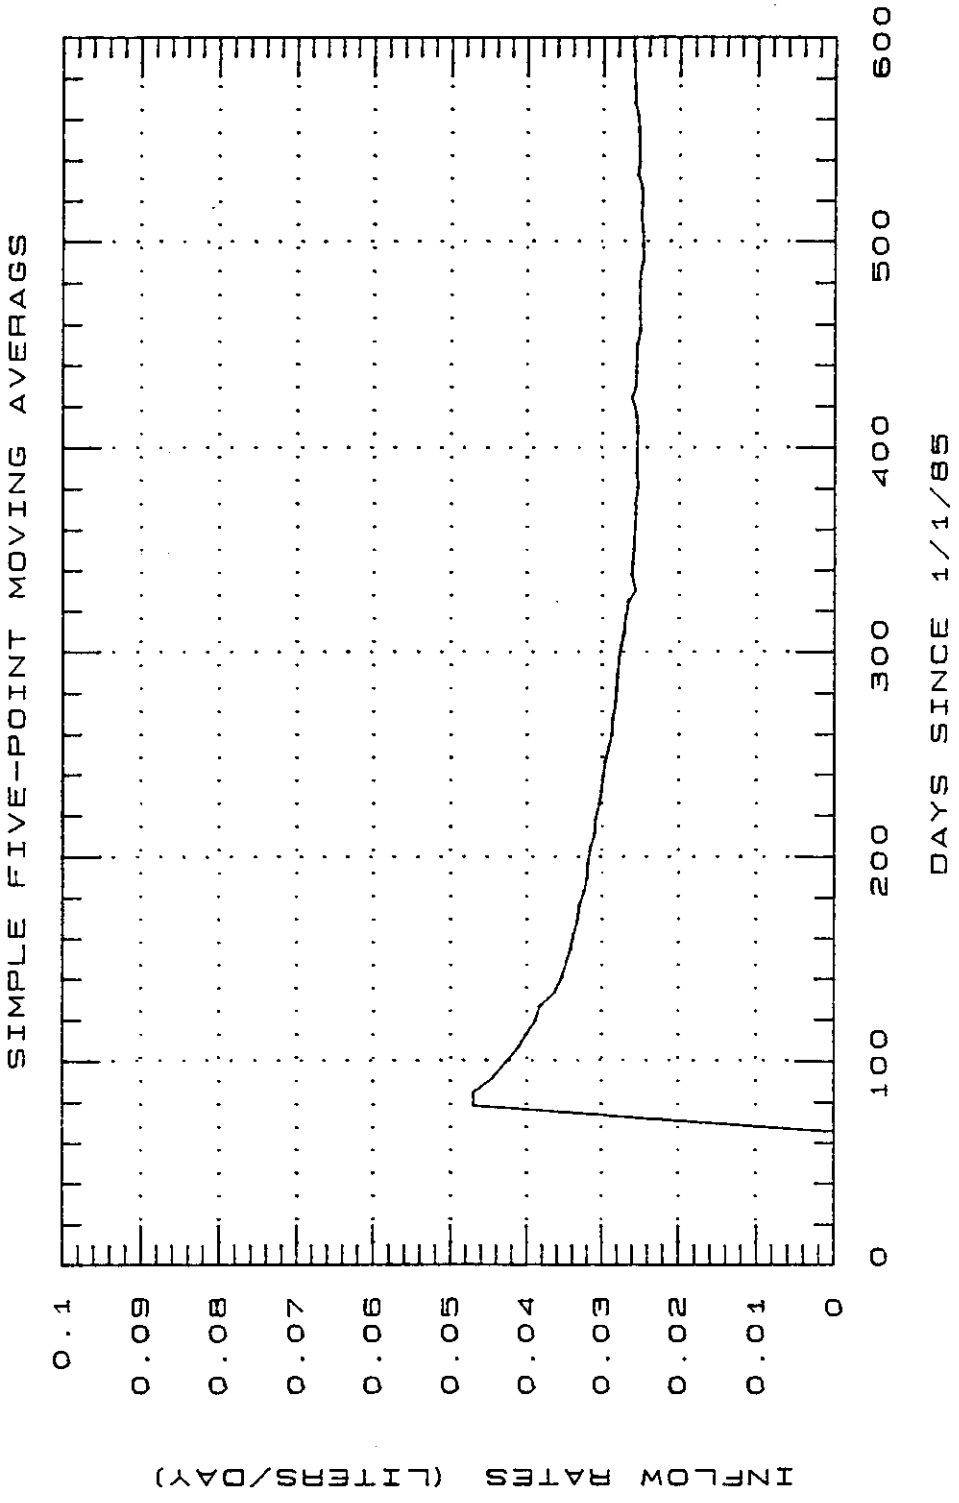

Figure D-9.

A1X01 Inflow Rates

3.3.4 Room A2, Hole A2X02

Hole A2X02 is an uphole completed February 20, 1985, in the north end of Room A2, directly over Hole A2X01. The drillers noted that the hole produced brine during drilling at both 3.5 meters and 7.7 meters. The hole was reamed on February 13, 1985, to a 12.7 centimeter (5-inch) diameter for the first 7.6 meters to eliminate drilling problems caused by moist cuttings.

A collecting device was installed on the hole February 19, 1985. The same difficulties described for Hole A1X02 were encountered, and the same cautions concerning the use of the data are applicable. A moist area immediately developed on the back (roof) around the hole and was about 1.5 meters in diameter on March 12, 1985. The irregularities in the data are mostly the result of problems in collecting the brine. A large amount of brine is known to have been lost by evaporation. Inflow rates were over 0.03 liters per day in March 1985, but then decreased to less than 0.01 liters per day (Table E.4, Figure D-12). Problems with the collecting device from April through August 1985 resulted in most of the brine inflows escaping and not being recorded, so the low readings during that time period do not reflect the fact that considerable brine flowed from Hole A2X02. Flow does appear to have been much lower during the winter of 1985-86, but shows an increase in the summer of 1986 to more than about 0.015 liters per day. Figure D-12 shows trends that roughly parallel the humidity measurements taken in the room, but the above-mentioned collecting uncertainties caution against drawing too strong a correlation.

Approximately 3.35 liters of brine had been collected from Hole A2X02 by August 19, 1986. A significant additional amount was certainly produced from the hole but lost by dissipation near the borehole collar and evaporation to the repository atmosphere.

3.3.5 Room A3, Hole A3X01

Hole A3X01 is a downhole completed on January 14, 1985 in the south end of Room A3. No brine or gas inflows were noted during drilling, but moist, irregular vugs were observed in the core, usually in coarsely crystalline polyhalitic halite, clear halite, and halite containing some brown clay. Brine accumulations were noticed shortly after drilling. Brine-soaked muck was noticed in this hole on February 5, 1985. Approximately 0.3 liters of brine, muck, and oil was removed from the hole on February 19, 1985 (Table E.5). Inflow rates in February and March were on the order of 0.03 liters per day, decreasing gradually through October 1985, and then maintaining a fairly constant inflow slightly greater than 0.02 liters per day through August 1986 (Table E.5, Figure D-13). Over 13.6 liters of brine had been removed from A3X01 by August 19, 1986.

3.36 Room A3, Hole A3X02

Hole A3X02 is an uphole completed January 22, 1985 in the south end of Room A3, directly over Hole A3X01. No brine or gas inflows were noted during drilling, but moist, irregular vugs were observed in the core, usually in coarsely crystalline polyhalitic halite, clear halite, and halite containing some brown clay. Brine accumulations were noticed shortly after drilling. A collecting device was installed February 5, 1985 and on February 19, 1985, over 0.1 liters of brine had accumulated in the collection container. The wet

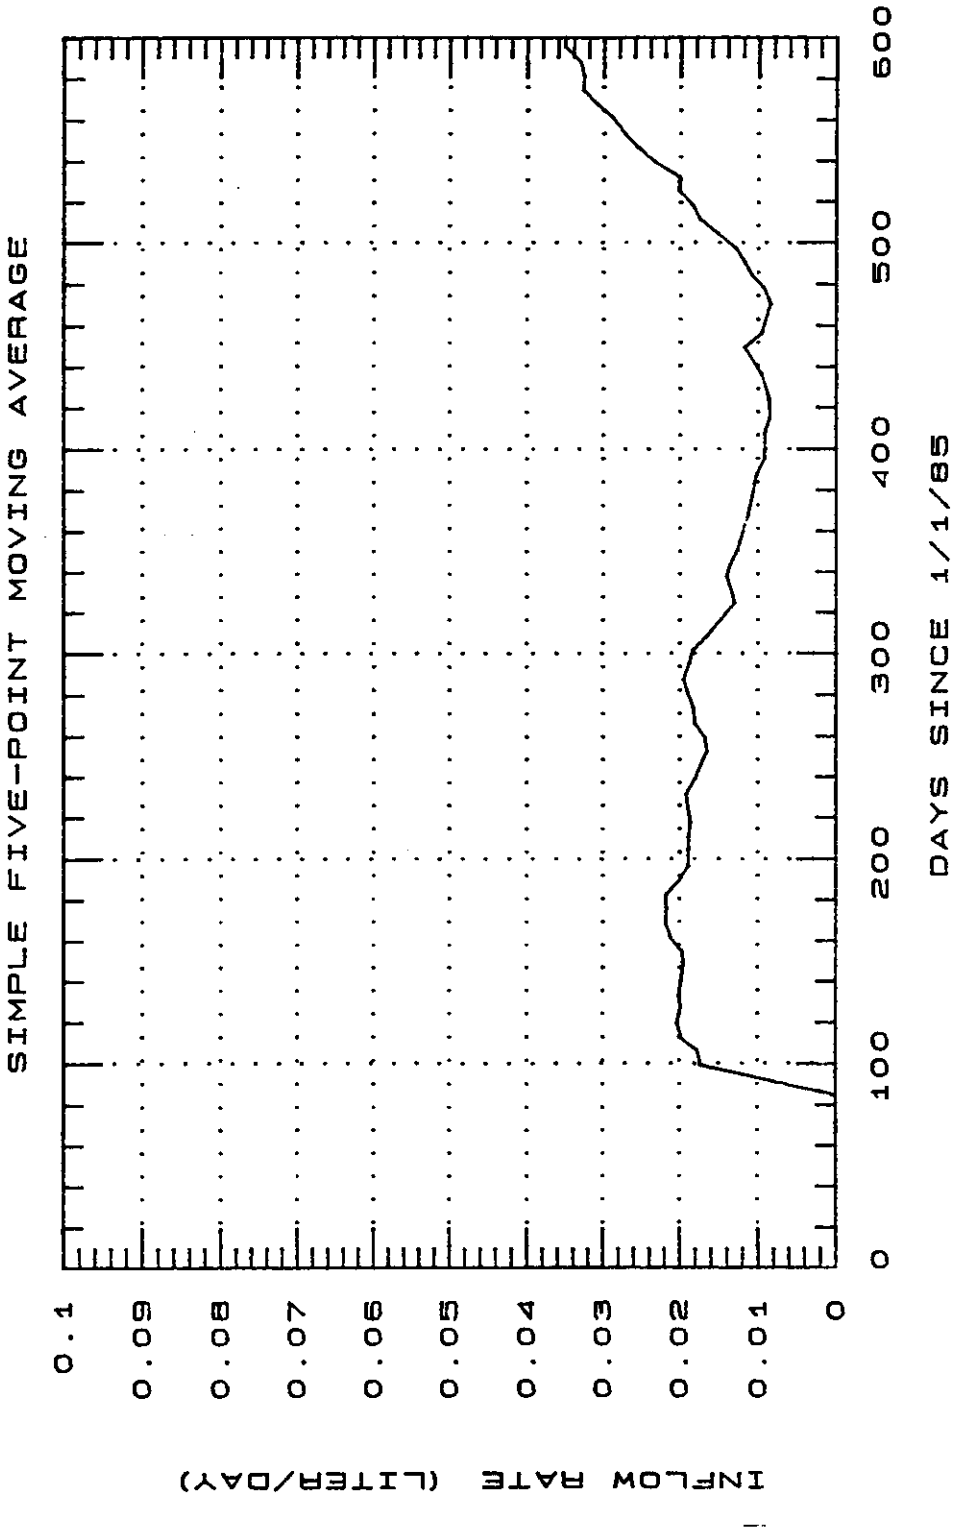

Figure D-10.

A2X01 Inflow Rates

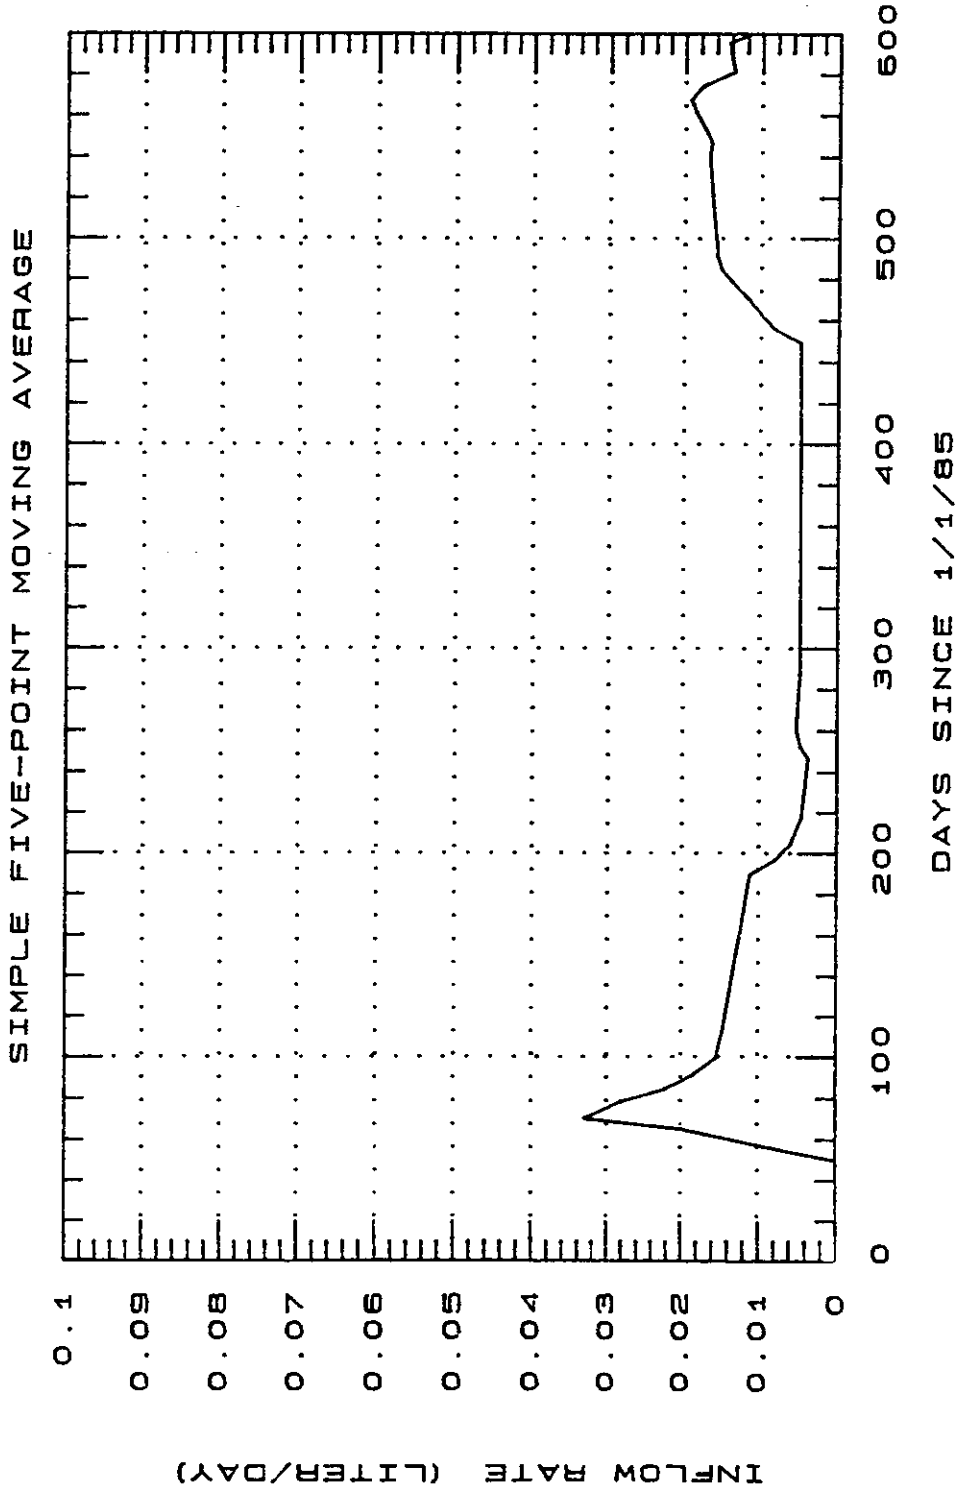

Figure D-12

A2X02 Inflow Rates

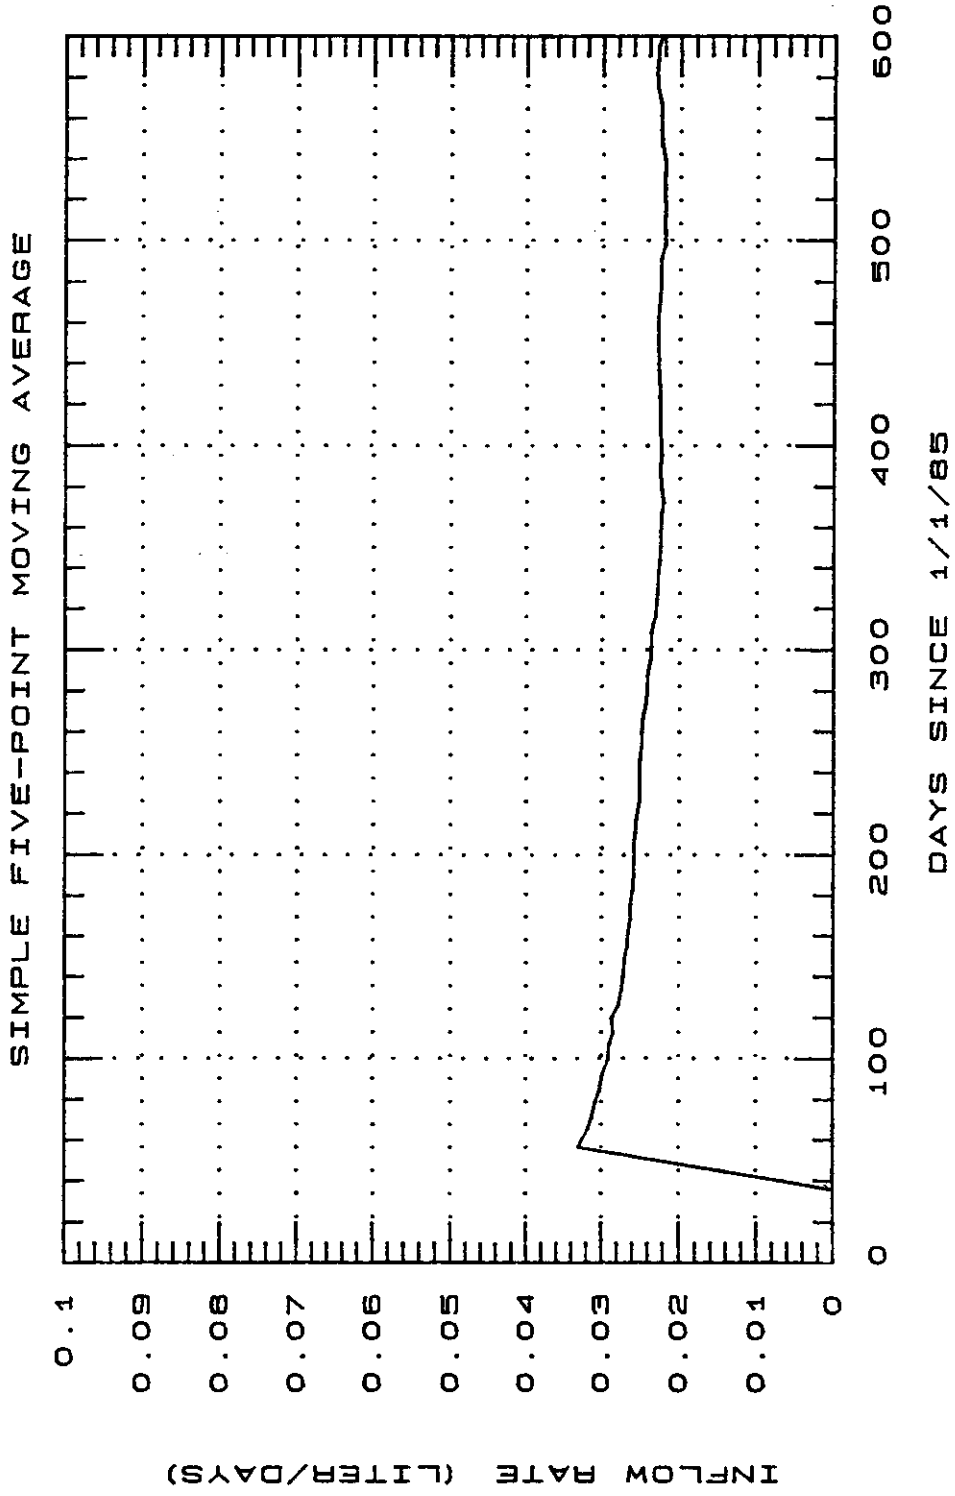

Figure D-13.

A3X01 Inflow Rates

area on the back (roof) was 3 feet in diameter by February 26, 1985. Inflow rates exceeded 0.02 liters per day in March 1985, declined slowly to about 0.01 liters per day in October 1985, and then declined more rapidly to trace amounts (0.01 liters per day or less) by the end of January 1986 (Table E.6, Figure D-14). A total of approximately 4.4 liters of brine had been collected by the end of January 1986, when significant inflows effectively ceased. An additional amount was certainly produced from the hole but lost by dissipation near the borehole collar and evaporation into the repository atmosphere.

3.3.7 Room B, Hole BX01

Hole BX01 is a downhole completed on January 27, 1985 in the north end of Room B. Marker Bed 139 was penetrated from 7.09 to 7.91 meters. When the core from 10.7 to 11.1 meters was removed from the core barrel, it was visibly wet with brine, and brine dripped from the fresh core. This interval consisted of clear to light reddish-orange, coarsely crystalline halite and polyhalitic halite. Moist, irregular vugs were observed in the core, usually in coarsely crystalline polyhalitic halite, clear halite, and halite containing some brown clay. Brine accumulations were noticed shortly after drilling. Approximately 0.4 liters of brine and muck were bailed from the hole on February 5, 1985 (Table E.7). Inflow rates in February 1985, were on the order of 0.1 liters per day, declining to about 0.06 liters per day by the end of April 1985 (Table E.7, Figure D-15). Inflow rates then continued through August 1986, showing only a slight decline to about 0.05 liters per day. A total of over 32 liters had been collected from BX01 by August 19, 1986.

3.3.8 Room B, Hole BX02

Hole BX02 is an uphole completed February 1, 1985 in the north end of Room B, directly over Hole BX01. Some moisture was noted on the core at 2.9 meters, but presented no problems to the drilling operations. The drillers noted that the hole was dry at completion of the drilling. Moist, irregular vugs were observed in the core, usually in coarsely crystalline polyhalitic halite, clear halite, and halite containing some brown clay. A collecting device was attached to the collar of the hole on February 5, 1985, and a few drops of brine were observed in the collecting container on March 12, 1985. On March 20, 1985, about 0.1 liter was removed from the collecting device (Table E.8). In April 1985, the inflow rate was on the order of 0.02 liters per day, declining gradually to about 0.015 liters per day in June 1985 (Table E.8, Figure D-16). Inflow then declined abruptly so that by the end of July 1985, only trace amounts were noticed. The evaporation problem has been exacerbated by the increasing air temperatures that began to develop in this room after the heaters were turned on. A total of about 1.75 liters of brine were collected from BX02 by the middle of January 1986. An additional amount was certainly lost by dissipation near the borehole collar and evaporation to the repository atmosphere, and the hole has been essentially dry since the end of January 1986.

3.4 Room G

Room G extends farther to the northwest than any of the rest of the WIPP underground workings (Figure D-1). It was excavated in November through December 1984. Four pairs of 15-meter up and down, vertical, stratigraphic observation holes were drilled to obtain geologic cores. These holes were

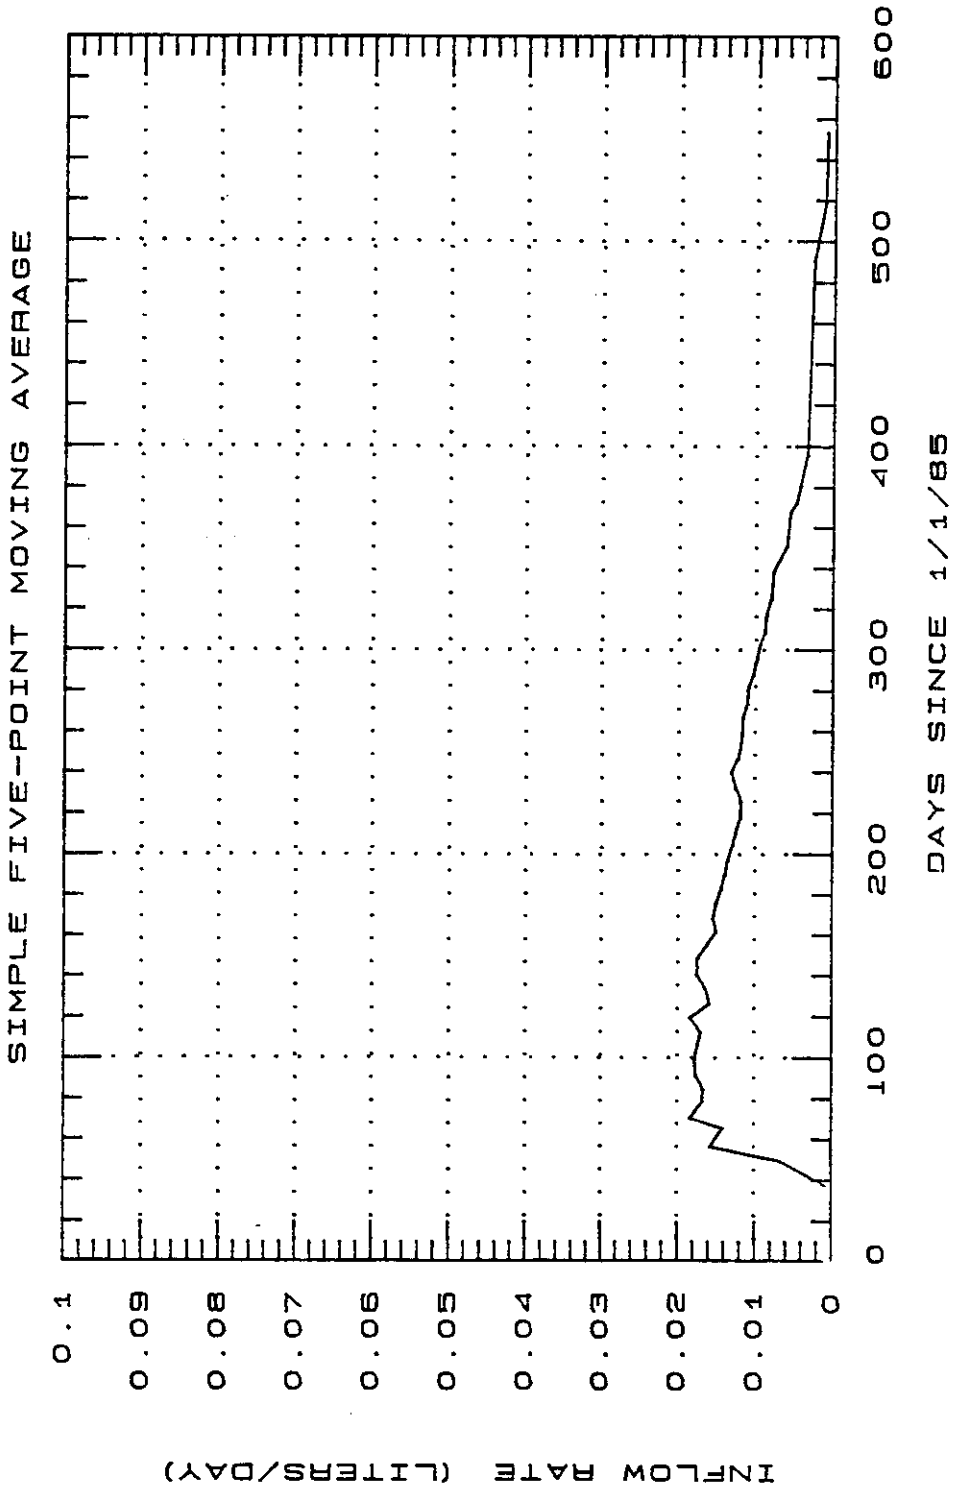

Figure D-14

A3X02 Inflow Rates

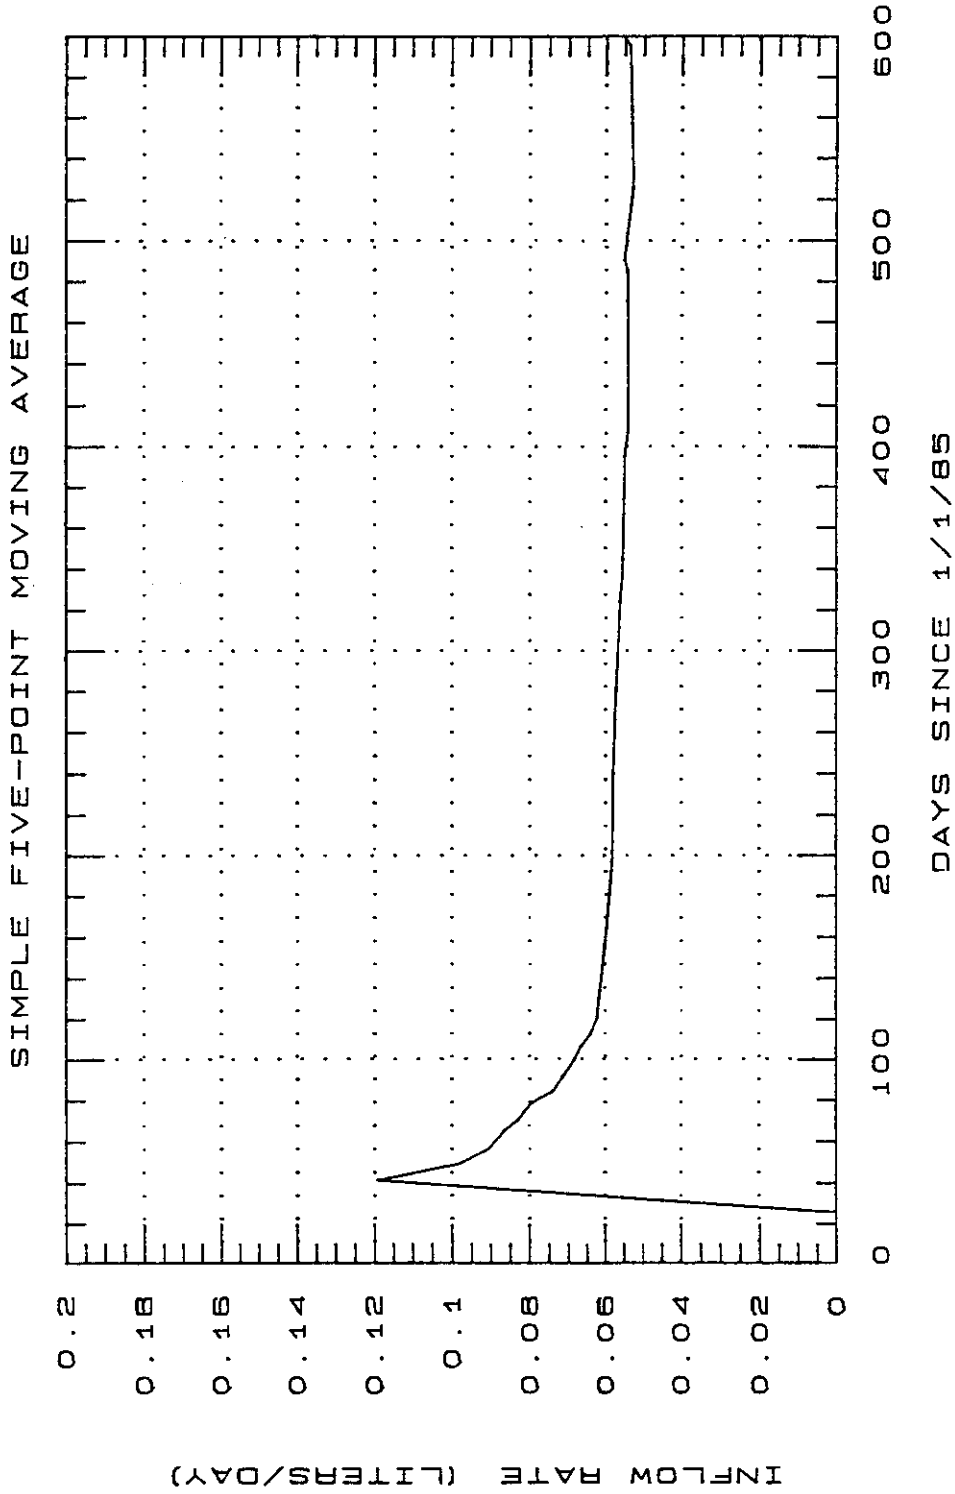

Figure D-15.

BX01 Inflow Rates

drilled with air as the drilling fluid. They were monitored from the time of drilling as part of the BSEP. The numbering system used assigned odd numbers to the upholes (DH35, DH37, DH39, and DH41) and even numbers to the corresponding downholes (DH36, DH38, DH40, and DH42). As a result of poor core recovery from the 6- to 12-meter interval in the westernmost downhole, DH42, an offset hole, DH42A, was drilled 12 meters deep, 2 meters west of DH42. It is interesting to note the striking difference in the inflow into this pair of holes, only 2 meters apart. Marker Bed 139 was generally intersected at depths of about 1.4 to 2 meters below the floor of Room G (Figure D-2).

3.4.1 Hole DH36

Hole DH36 is the easternmost downhole in Room G and was completed January 26, 1985. No brine or gas inflows were noted during drilling, but brine accumulations were noticed shortly after drilling. Moist muck was observed in the bottom of the hole on January 28, 1985 and 2.5 liters of brine, muck, and hydraulic fluid (contamination from drilling) were bailed from the hole on February 5, 1985 (Table E.10). Initial inflow rates were on the order of 0.25 liters per day and remained quite steady, decreasing only slightly through August 1986, when inflow rates still exceeded 0.2 liters per day (Table E.10, Figure D-17). Almost 125 liters of brine had been removed from DH36 by August 19, 1986.

3.4.2 Hole DH38

Hole DH38 is a downhole completed January 26, 1985 just east of the center of Room G. No brine or gas inflows were noted during drilling, but brine accumulations were noticed shortly after drilling. Moist muck was observed in the bottom of the hole on February 5, 1985 and 0.8 liters of brine and muck were bailed from the hole on February 19, 1985 (Table E.12). Initial inflow rates exceeded 0.1 liters per day in February 1985, but by mid-March had declined to less than 0.06 liters per day (Table E.12, Figure D-18). Inflow rates show a slightly increasing trend through October 1985, followed by a slightly decreasing trend through August 1986, but overall the inflow rate has been remarkably steady. Over 34 liters of brine had been removed from DH38 by August 19, 1986.

3.4.3 Hole DH40

Hole DH40 is a downhole completed January 25, 1985 just west of the center of Room G. No brine or gas inflows were noted during drilling, but brine accumulations were noticed shortly after drilling. Moist muck was observed in the bottom of the hole on February 5, 1985 and about a liter of brine, muck, and hydraulic fluid was bailed from the hole on April 17, 1985 (Table E.13). Calculated inflow rates in April 1985 exceeded 0.04 liters per day but quickly decreased to about 0.01 liters per day in May, then decreased only gradually through August 1986 (Table E.13, Figure D-19). A total of slightly more than 4.3 liters had been removed from DH40 by June 3, 1986.

3.4.4 Hole DH42

Hole DH42 is a downhole completed on January 23, 1985 at the west end of Room G. No brine or gas inflows were noted during drilling, but brine accumulations were noticed shortly after drilling. Moist muck was observed in the

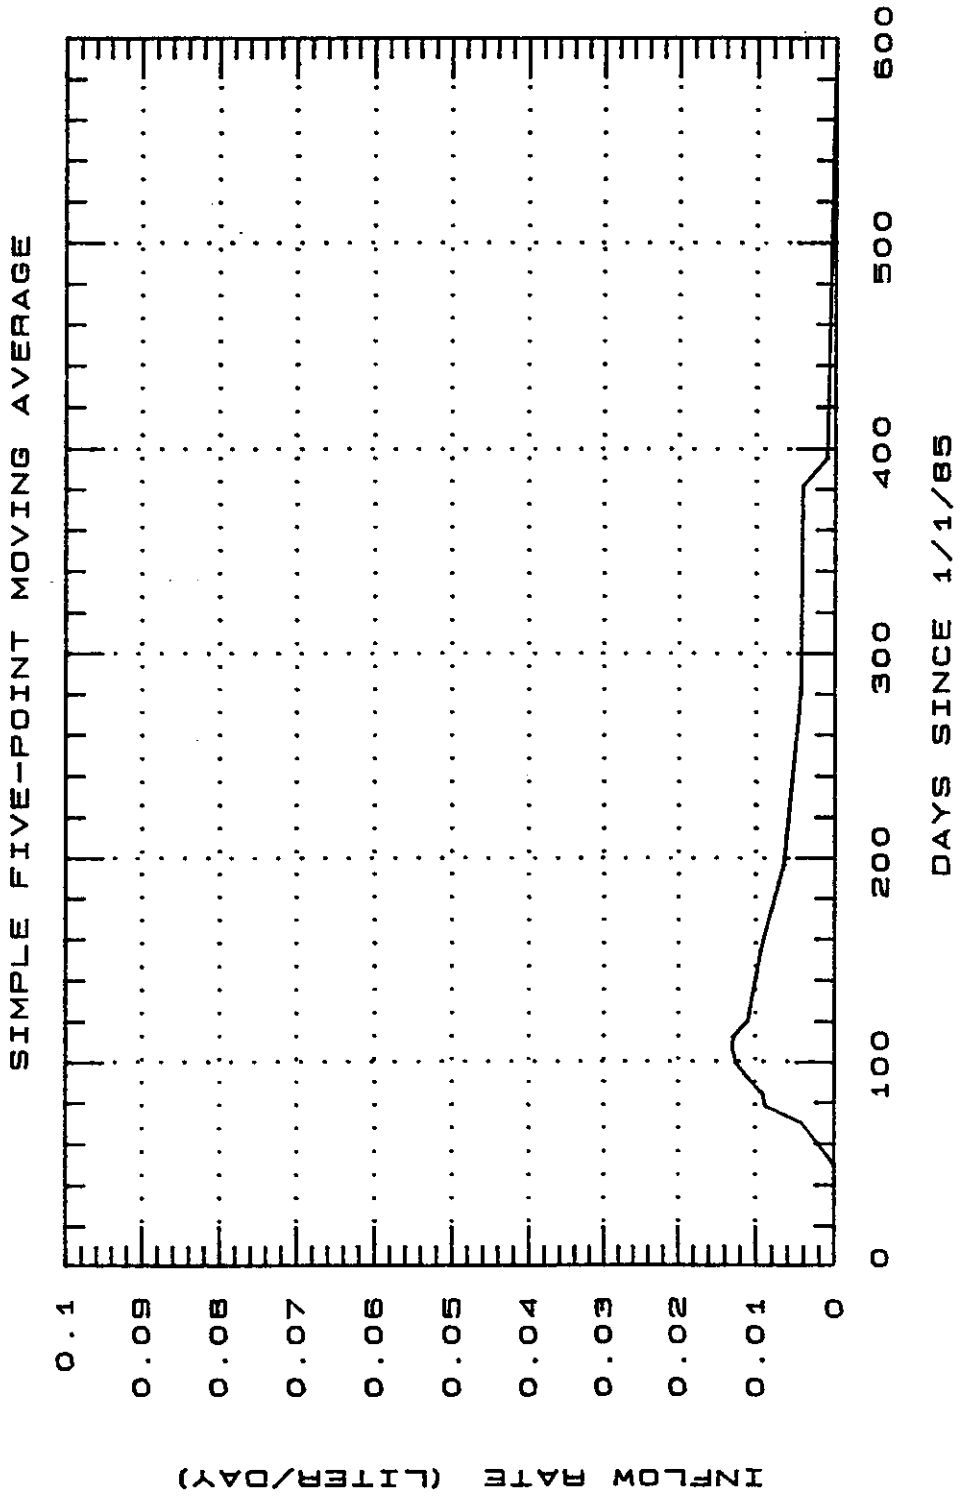

Figure D-16.

BX02 Inflow Rates

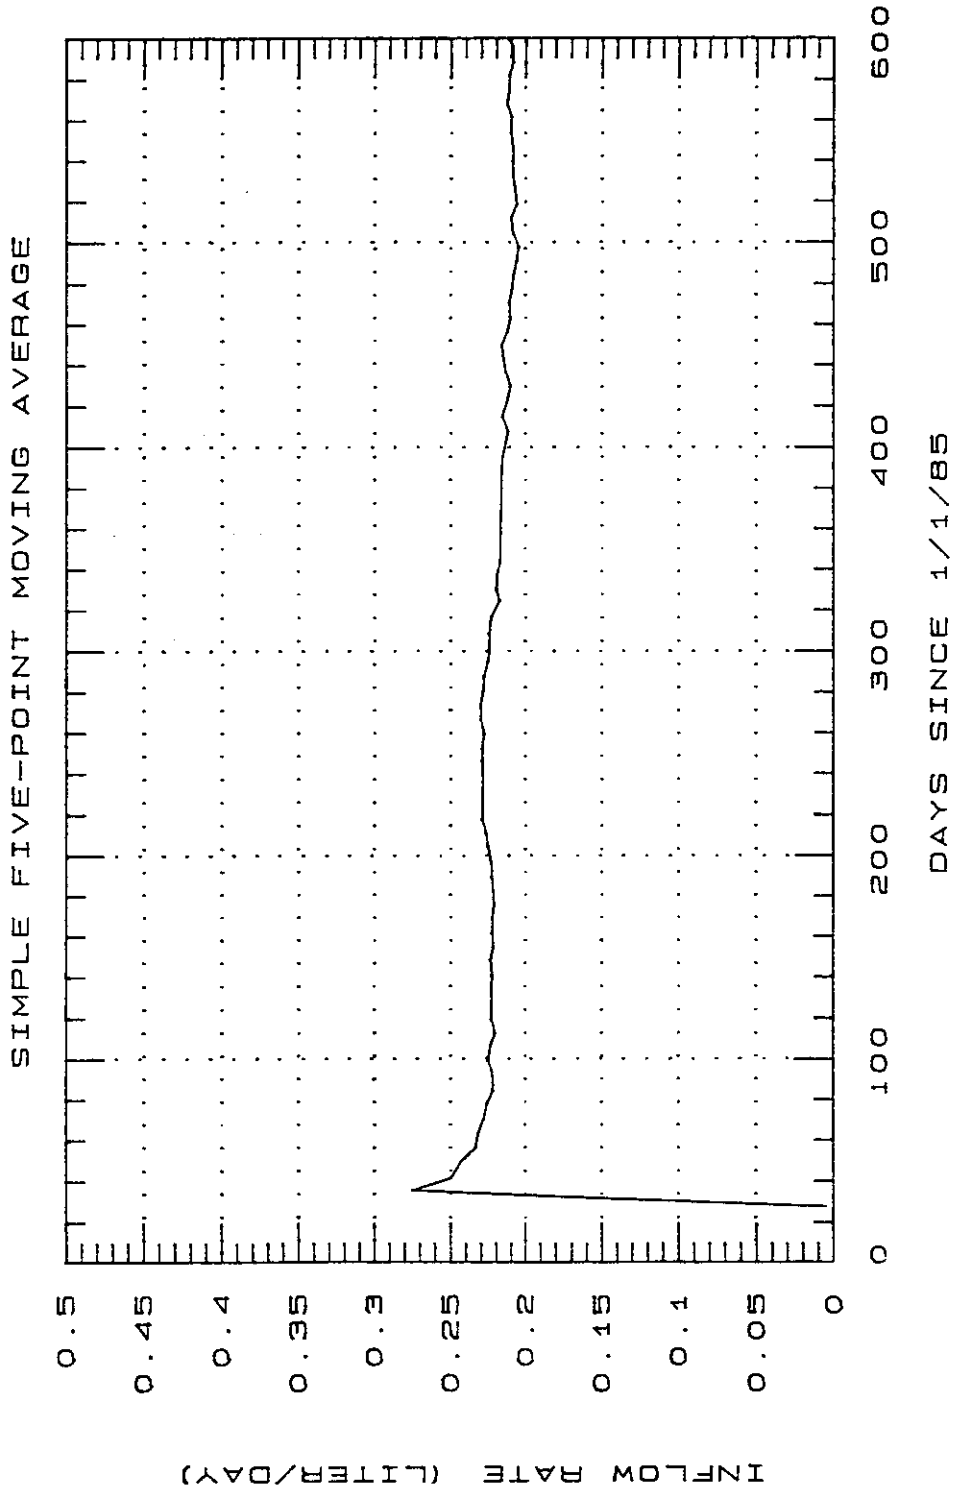

Figure D-17

DH36 Inflow Rates

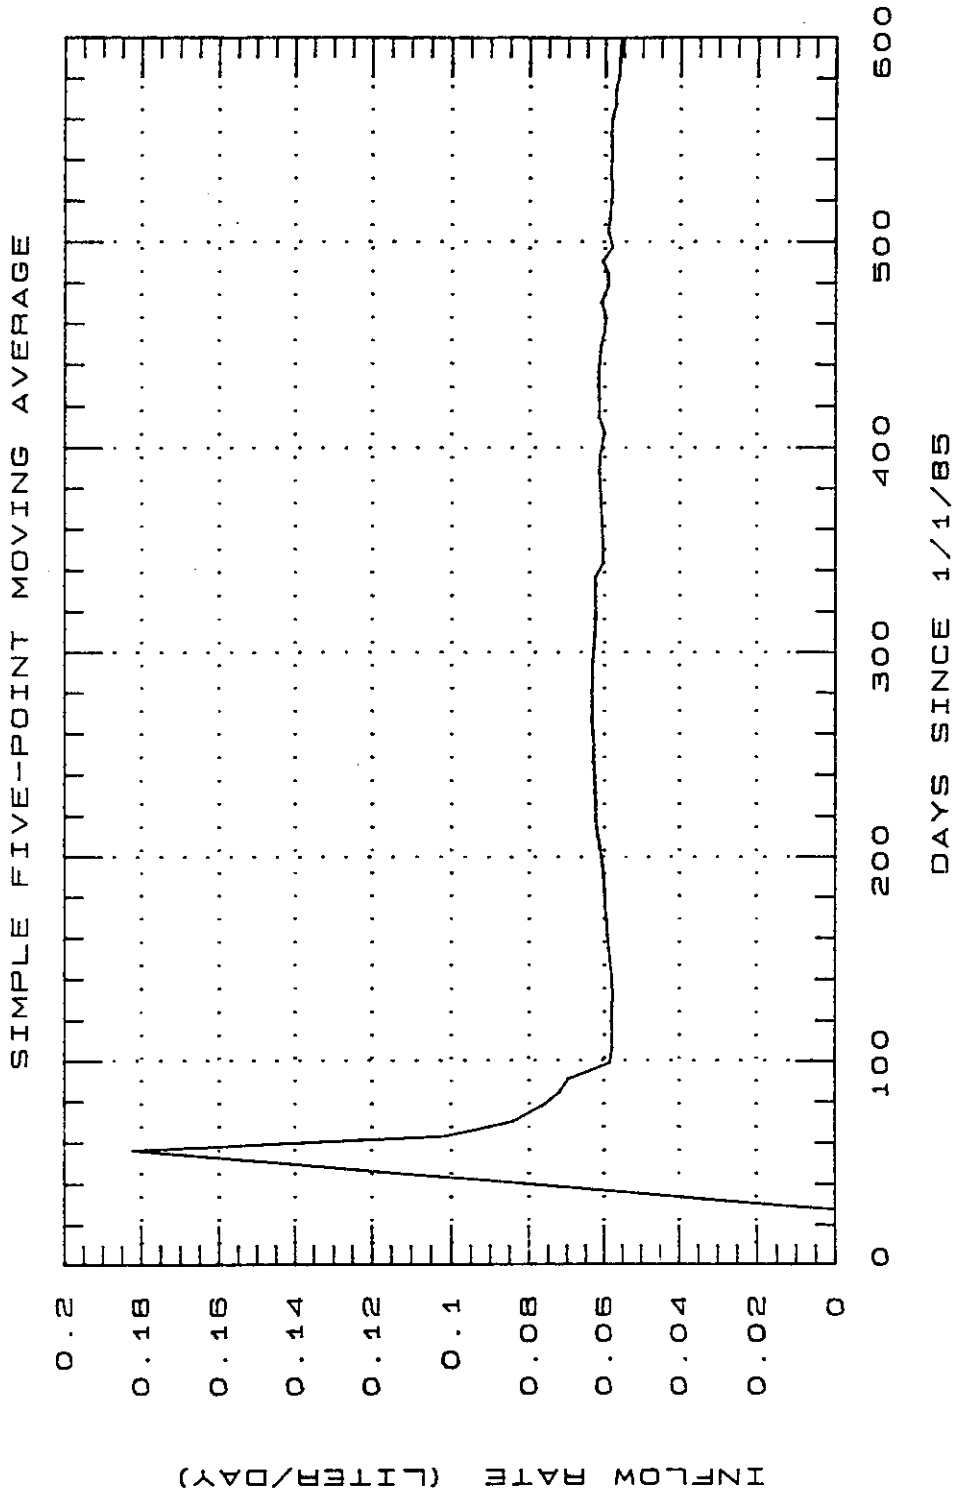

Figure D-18.

DH38 Inflow Rates

bottom of the hole on January 28, 1985 and about 0.3 liters of brine and muck was bailed from the hole on February 5, 1985 (Table E.14). Calculated inflow rates in mid-February 1985, were on the order of 0.05 liters per day and decreased only gradually to about 0.03 liters per day through August 1986 (Table E.14, Figure D-20). A total of approximately 19 liters had been removed from DH42 by August 19, 1986.

3.4.5 Hole DH42A

Hole DH42A is the westernmost downhole at the west end of Room G, 2 meters west of DH42. This hole was drilled because of poor core recovery from the 6- to 12-meter interval in DH42, which is 15.6 meters deep. DH42A was completed January 25, 1985 and is 12.3 meters deep. No brine or gas inflows were noted during drilling, but brine accumulations were noticed shortly after drilling. Brine was observed in the bottom of the hole on January 28, 1985 and 0.85 liters of brine were bailed from the hole on February 5, 1985 (Table E.15).

Calculated inflow rates in mid-February 1985, were on the order of 0.18 liters per day, increased gradually to about 0.2 liters per day in May 1985, and then began decreasing to about 0.1 liters per day in April 1986, where the inflow rate appeared to level out (Table E.15, Figure D-21). A total of approximately 75 liters of brine had been removed from DH42A by August 19, 1986. It is interesting to note that approximately four times as much brine flowed into DH42A than into DH42, which is 2 meters to the east and 3.3 meters deeper.

Most of the downholes studied showed an initial period of little or no inflow followed by a brief maximum inflow period lasting for a few days or a week or two, followed in turn by a decreasing inflow trend. Hole DH42A is the only location studied during Phase I that exhibited an early inflow trend that increased gradually over a much longer period of time (three months). The decreasing trend that followed also took much longer to begin to level out to a fairly steady inflow rate (Figure D-21).

3.4.6 Hole DH35

Hole DH35 was completed January 25, 1985 and is the easternmost uphole at the east end of Room G, above Hole DH36. No brine or gas inflows were noted during drilling, but brine accumulations were noticed shortly after drilling. Brine was observed dripping from the collar on February 5, 1985. A collecting device was installed under the collar on that date, and almost 0.2 liters was collected on March 5, 1985. Inflow rates were in excess of 0.02 liters per day in mid-March 1985, and decreased fairly steadily to 0.01 liters per day in May 1986 (Table E.9, Figure D-22). The lack of brine collected in late May and early April 1986, reflects the fact that the collecting device was broken, not that inflow ceased. However, a marked decrease in inflow did take place about that time. Calculated inflow rates in the summer of 1986 were less than 0.05 liters per day and seemed to be reduced to trace amounts by late August 1986. A total of approximately 4.3 liters was collected from DH35 by August 19, 1986.

3.4.7 Hole DH37

Hole DH37 was completed January 26, 1985 and is located just east of the center of Room G, above Hole DH38. No brine or gas inflows were noted during

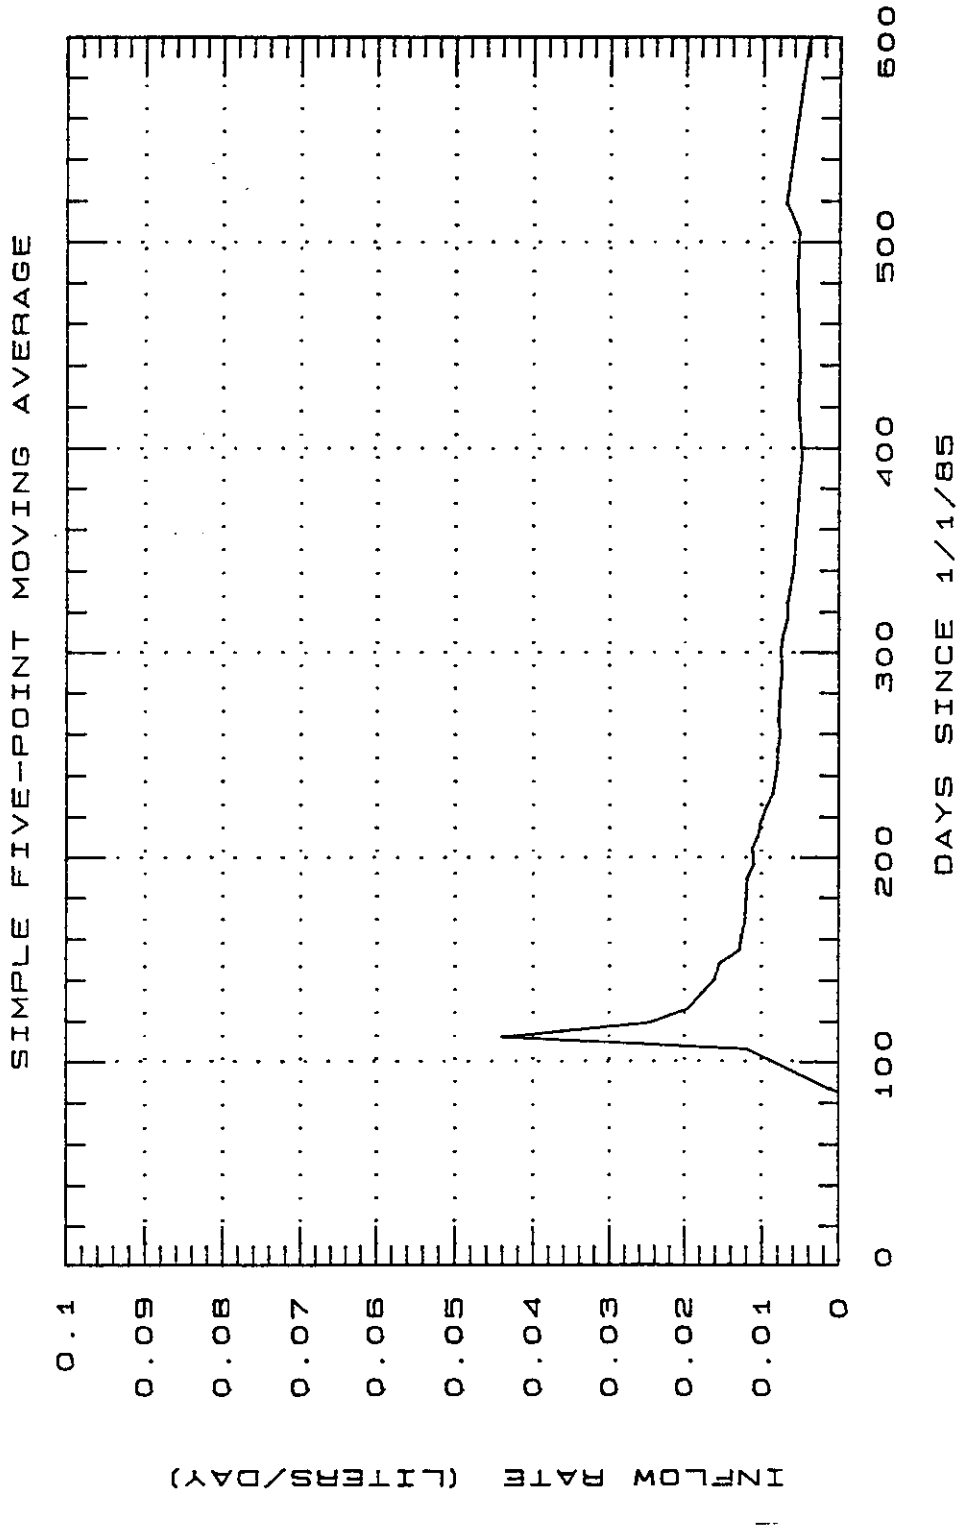

Figure D-19

DH40 Inflow Rates

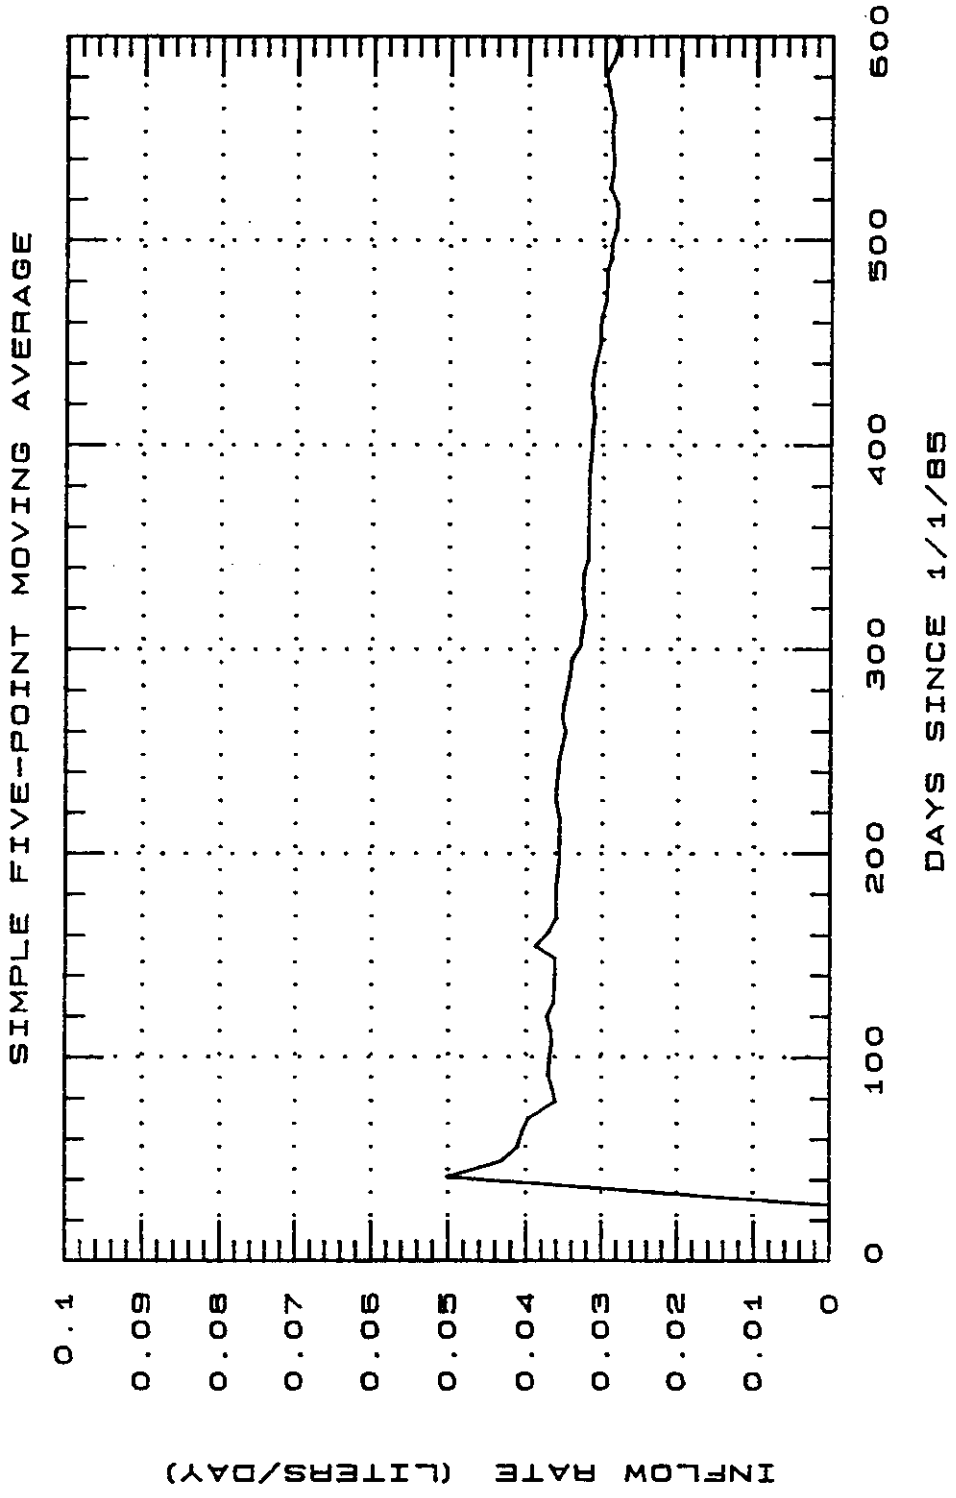

Figure D-20.

DH42 Inflow Rates

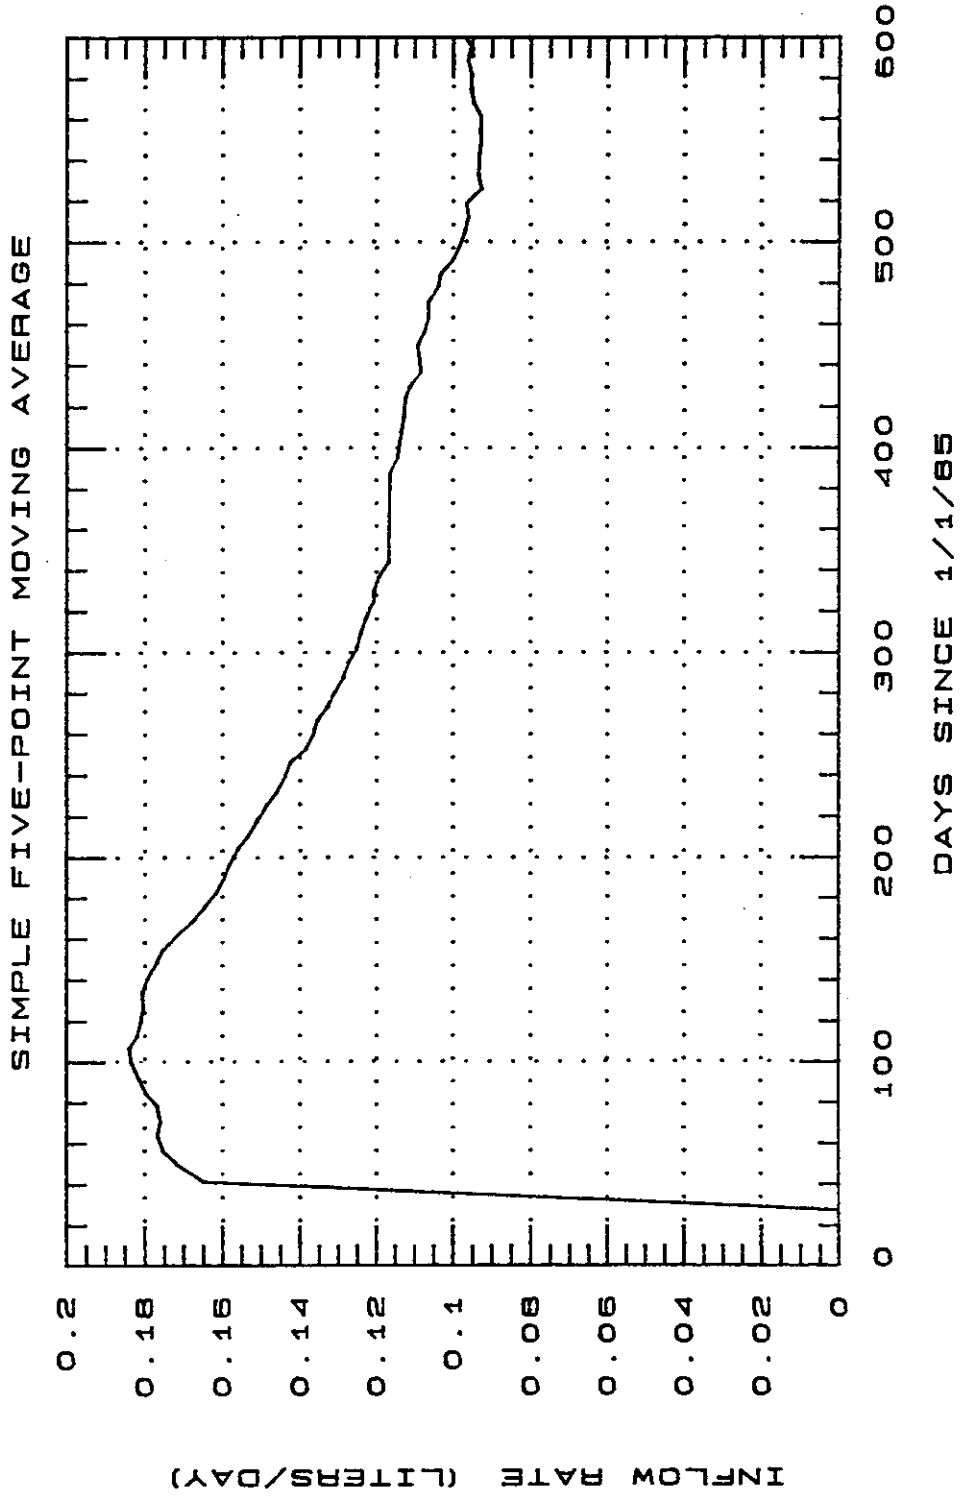

Figure D-21

DH42A Inflow Rates

drilling, but brine accumulations were noticed shortly after drilling. Brine was observed dripping from the collar on February 5, 1985. A collecting device was installed under the collar on that date, and approximately 0.06 liters was collected on March 5, 1985. Inflow rates were on the order of 0.01 liters per day through July 1985, decreasing to less than 0.005 through September 1985, and then decreased further to trace quantities accumulating in the collecting container (Table E.11; Figure D-23). A total of a little over 1.2 liters was collected from DH37 by July 1, 1986.

3.4.8 Hole DH39

Hole DH39 was completed January 24, 1985 and is located just west of the center of Room G, above Hole DH40. No brine or gas inflows were noted during drilling, but brine accumulations were noticed shortly after drilling. A moist area on the back (roof) around the collar was observed on February 5, 1985. A collecting device was installed under the collar on that date, and trace amounts of brine were collected in May 1985. Measurable quantities of brine did not accumulate in the collecting device.

3.4.9 Hole DH41

Hole DH41 was completed January 25, 1985 at the west end of the center of Room G, above Hole DH42. No brine or gas inflows were noted during drilling, but brine accumulations were noticed shortly after drilling. A moist area on the back (roof) around the collar was observed on February 5, 1985. A collecting device was installed under the collar on that date. Measurable quantities of brine did not accumulate in the collecting device.

3.5 Room J

Room J is the site of the Materials Interface Interactions Test (MIIT) and the Drum Durability Test (DDT). Room J was excavated in April 1984. A pit was excavated in the southwest floor of the room and a series of 1- to 2-meter deep drill holes were made in the north end of the room (Figure D-24; Morse and Hassinger, 1985). Brine flowed into Holes MIIT-2 and MIIT-4 during drilling, and began to seep into the pit immediately after excavation. The brine pit was cleaned and blown dry with compressed air on June 27, 1984. Five days later the pit had refilled to about one-half of its previous depth.

Forty shallow drill holes were made for the MIIT program. The fact that the brine levels in these closely-spaced drill holes were dramatically different was observed during the summer and fall of 1984. Holes partially or completely filled with brine were interspersed with dry or nearly dry holes, often less than a meter away. On October 26, 1984, the room and the brine accumulations were surveyed (Figure D-24; Morse and Hassinger, 1985). The brine levels in the drill holes were resurveyed on November 26, 1984. At that time, the floor of the room was observed to be contaminated by a variety of materials and fluids.

On November 29, 1984, the MIIT holes were evacuated and cleaned with compressed air, the DDT pit was cleaned, and the contaminants that were loose on the floor removed. Approximately 75 liters of brine and salt crystals were removed from

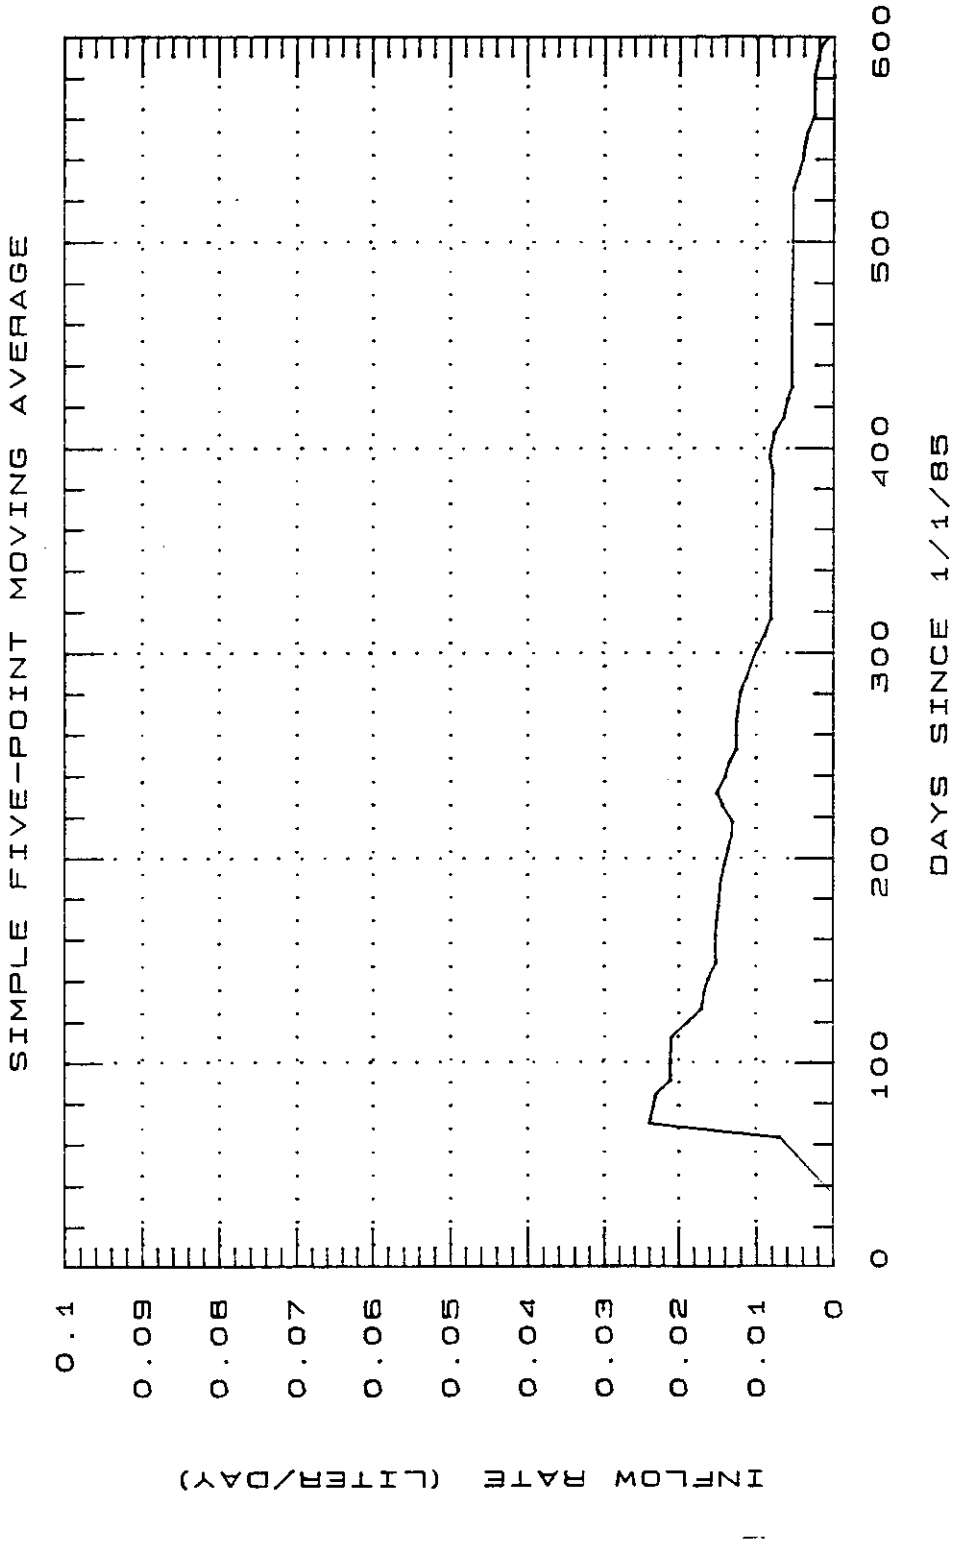

Figure D-22.

DH35 Inflow Rates

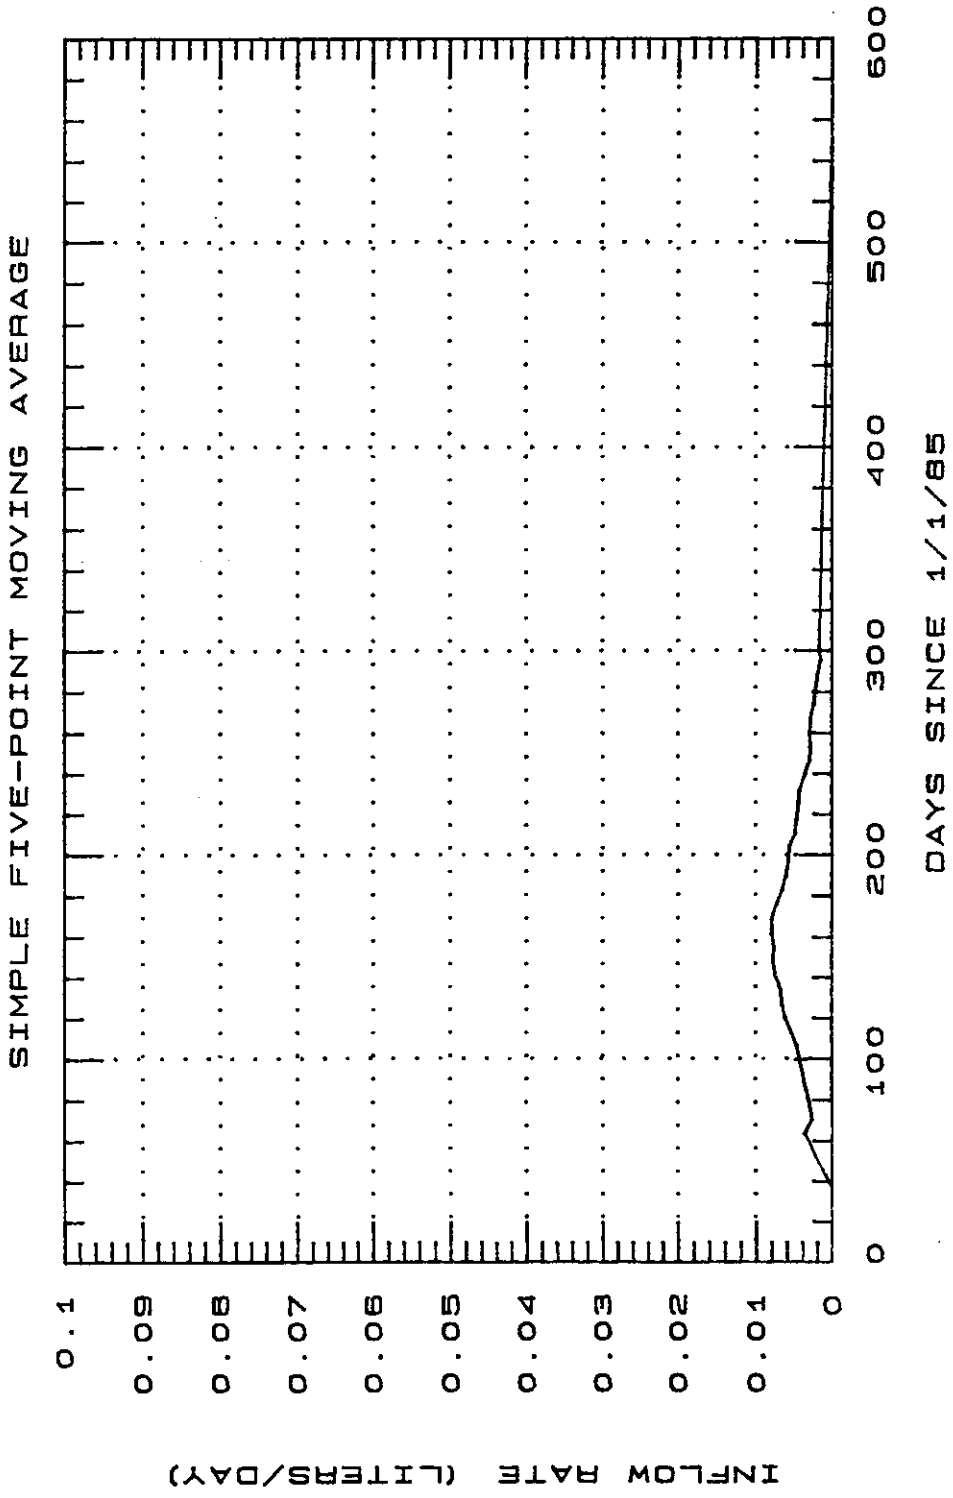

Figure D-23.

DH37 Inflow Rates

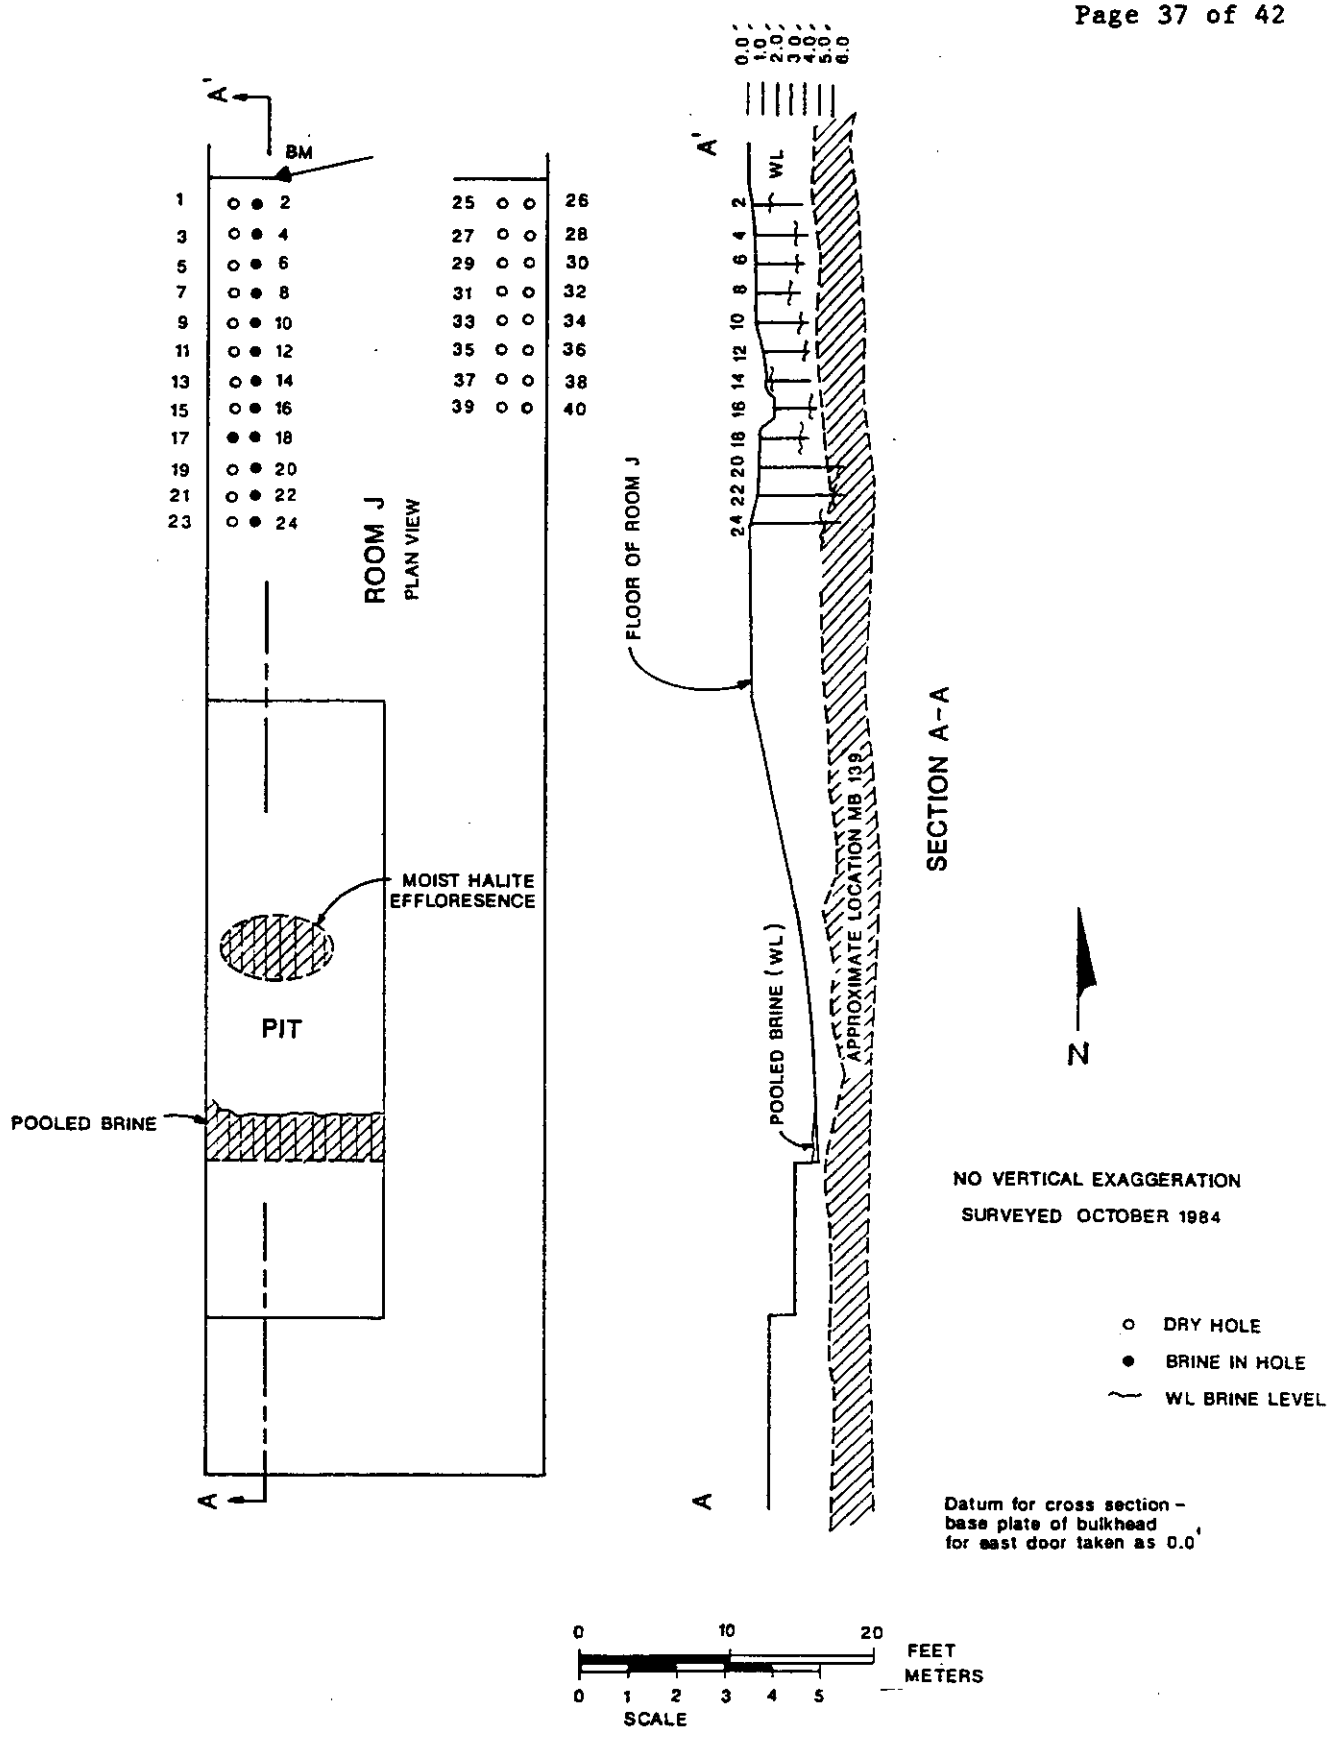

Figure D-24.

Room J Brine Survey, Plan and Cross Section
(After Morse and Hassinger, 1985)

the pit and about 17.5 liters were removed from the MIIT holes. Eighteen days later brine puddles had returned to the floor of the DDT pit and some brine had returned to all except one of the MIIT holes that had previously contained brine.

On January 8, 1985, the brine levels were again surveyed and the holes evacuated. Brine inflows were monitored through April 23, 1985, when Room J was closed to the BSEP in the course of the MIIT experiments.

The significance of the observations that were made in Room J is that drill holes less than a meter apart exhibited strikingly different brine inflows and the brine level in adjacent holes stood at strikingly different levels. Marker Bed 139 was obviously playing a significant role in the migration of brine to the MIIT holes and the brine pit (Figure D-24), and gas bubbles were associated with almost all occurrences. A total of over 18 liters of brine were removed from the MIIT holes.

3.6 Room L1, Hole L1X00

Room L1 was excavated in April 1984. Shortly after excavation, 11 holes were drilled in the floor across the north end of the room and approximately one foot of brine accumulated in each of these holes. On November 27, 1984 it was observed that 10 of the 11 holes had been filled and sealed with grout as part of the Plugging and Sealing test program. The remaining hole, L1X00, was still open and contained brine, and about 11 liters of brine were removed from the hole. On November 30, 1984 compressed air was used to completely evacuate the hole. On May 14, 1985 the hole was found to contain brine and an additional 11.46 liters were removed. Inflow rates at the end of May were calculated to be on the order of 0.03 liters per day, declining gradually to about 0.02 liters per day in early December 1985 (Table E.19, Figure D-25). Inflow rates then gradually increased through August 1986 returning almost to their May 1985, values. A total of over 23.5 liters of brine had been removed from L1X00 by August 19, 1986.

Thirty-six downholes, 10 centimeters in diameter, and 3.6 meters deep were drilled through MB 139 on a 1 meter by 1.5 meter grid in the north end of Room L1. Observations of brine inflows into some of these holes showed variations between holes that were similar to, but somewhat less dramatic than, those described above for the MIIT holes in Room J.

3.7 E140 Drift at S1950, Holes DH215 and DH216

The south exploratory drift was excavated at E140 in 1982 and 1983, reaching the southern end (S3666) of the planned underground facility January 29, 1983. The initial excavation was 2.4 meters high and 7.6 meters wide. The part of the drift at S1950 was mined on January 3, 1983. A pair of uphole and downholes (DH215 and DH216) were drilled shortly after excavation, and sonic-probe extensometers (GE247 and GE248) were installed in them. Both holes were drilled with brine as the drilling fluid and both encountered traces of pressurized gas during drilling. Hole DH215 is the uphole and is 15.8 meters deep. Hole DH216 is the downhole and is 16.5 meters long. Both holes began producing brine shortly after drilling and, partially because they were far removed from the observation holes in the northern, experimental part of the WIPP workings, were the location of early, informal, brine inflow observations.

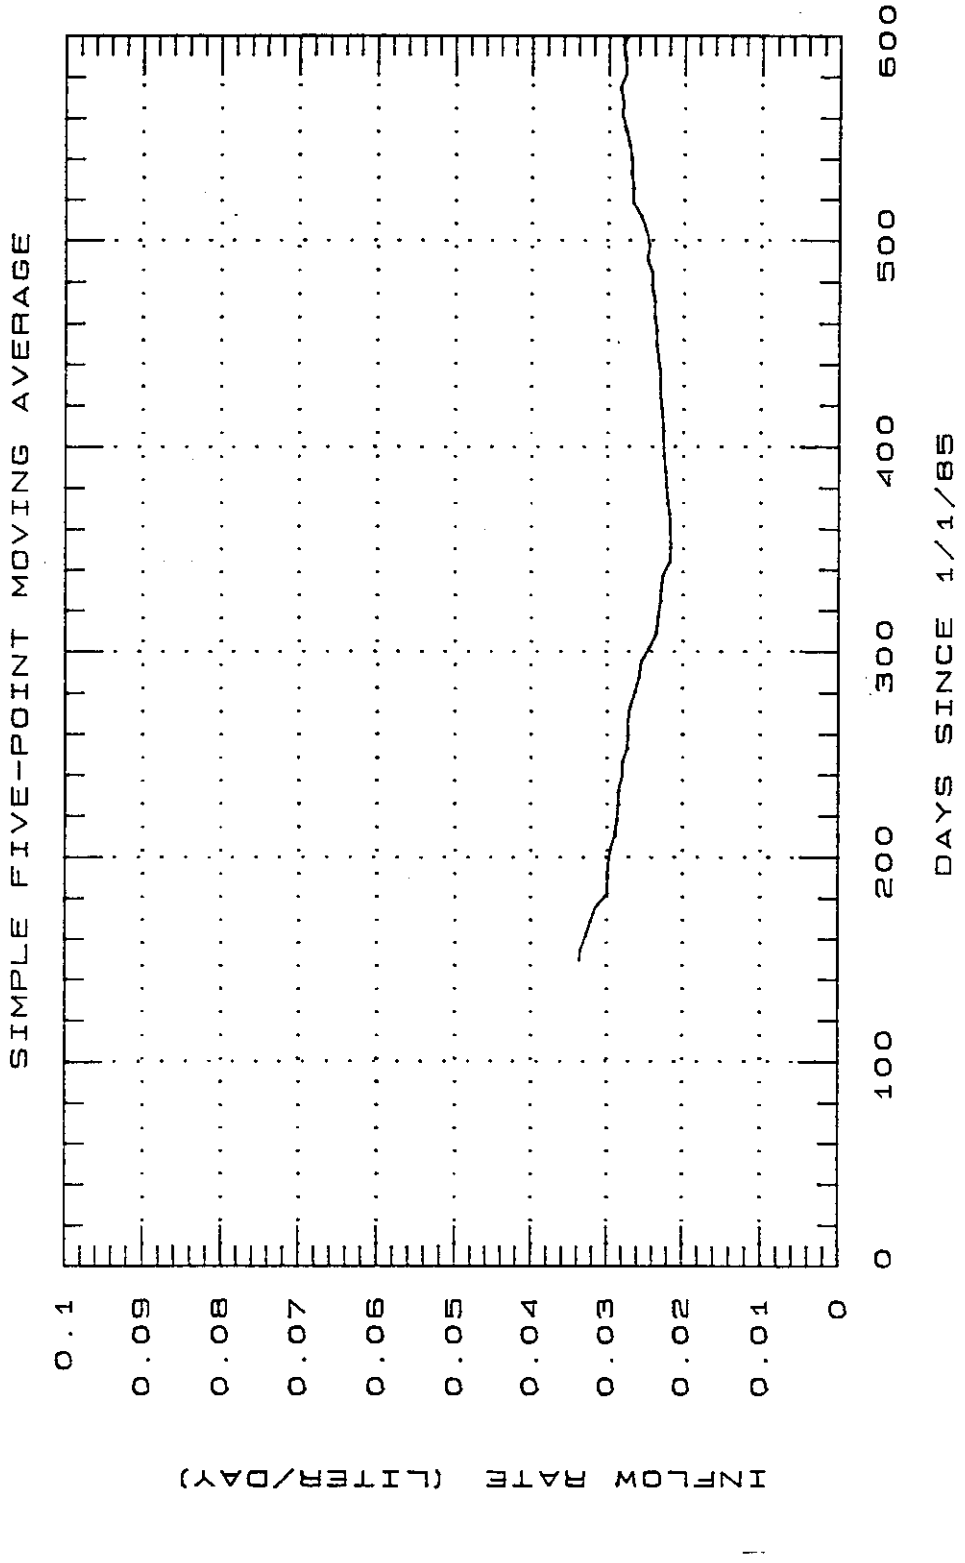

Figure D-25.

L1X00 Inflow Rates

The presence of instrumentation in both holes makes it difficult to obtain good quantitative data and probably effects any chemical data obtained from brine withdrawn from them.

In April 1984, the downhole was observed to be completely filled with brine, and brine was observed dripping into it from the uphole over it. It was not known how much of the 15.8 meters of brine in the downhole had been produced from the rocks exposed in the sides of the hole and how much had dripped into it from the uphole. It was further recognized that both holes had been drilled with brine and that water had been spread on the floor of the drift by the mining contractor for dust control, both possible sources of brine that may have accumulated in the downhole.

On April 20, 1984, a funnel and collecting device was installed on the uphole to collect the brine issuing from it, and the brine that filled the downhole was evacuated down to the level of the instrument head, approximately 0.55 meters below the collar. It was not possible to conveniently extract brine from below the instrument head, so a column of brine more than 15.2 meters long remained in the hole.

Three days later, on April 23, 1984, about an inch of brine had accumulated over the instrument head in the downhole (DH216), but no brine had been collected from the uphole (DH215). Gas bubbles were observed rising around the instrument head in DH216. By the end of April, small amounts of brine were collected from the uphole, and incidental observations throughout the summer and fall of 1984 documented that more brine was being produced from the downhole than from the uphole, but that both did yield brine.

Formal collections were initiated in January 1985, at which time the uphole seemed to be producing more brine than the downhole. Accurate data from the downhole (DH216) was difficult to obtain, and the collar was destroyed and the hole plugged by mining November 19, 1985.

Data from the uphole, DH215, is more complete (Table E.16) and is quite interesting (Figure D-26). Inflow rates in January 1985 were on the order of 0.01 liters per day and showed a gradual increase, almost doubling to 0.02 liters per day by November 1985. On November 19, 1985, the floor of E140 was lowered by 4 feet at S1950. On November 20, 1985, mining of the cross drift S1950 began, with mining to the east, toward E300. On January 29, 1986, the cross drift was extended to the west, toward W30. Hole DH215 was the uphole in the center of what then became the intersection of E140 and S1950. On February 28, 1986, additional mining took place at this intersection as the floor of E140 south of the intersection was lowered 1.2 meters.

Inflow rates increased three-fold, to approximately 0.06 liters per day, immediately following the lowering of the floor and the excavation of the cross drift to the east. It is highly probable that the change in the stress distribution in the vicinity of the intersection resulted in the increased inflow and that the sudden increase shown on Figure D-26 is a mining-induced transient effect. Inflow rates then declined steadily, perhaps beginning coincidentally with the additional mining at the intersection or perhaps related to that mining, through August 1986, to rates below those observed in January 1985.

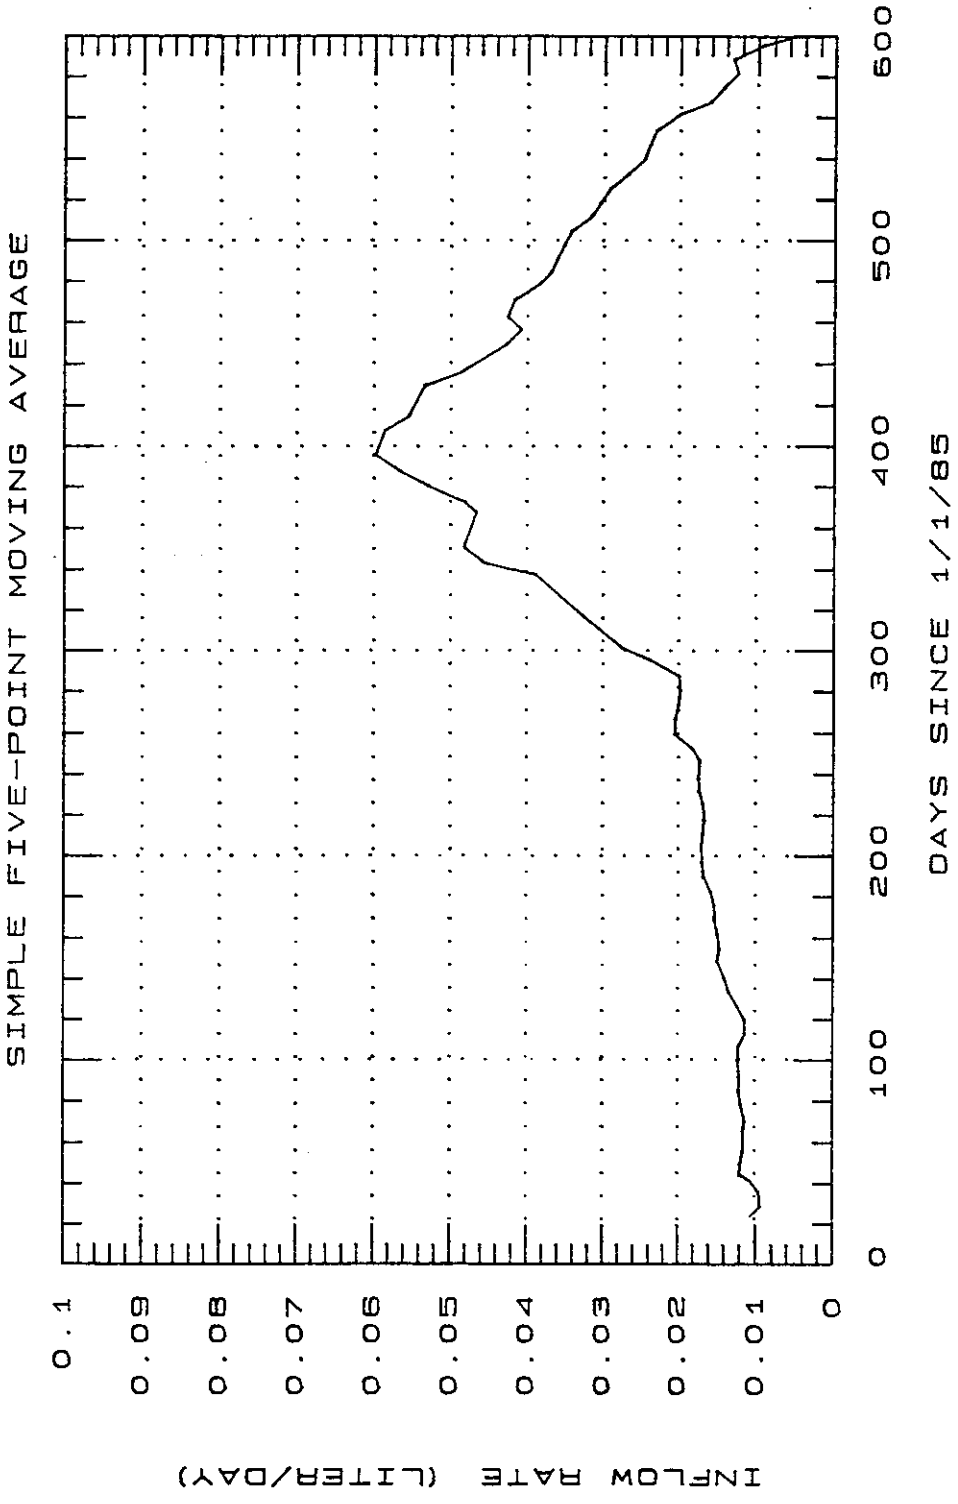

Figure D-26.

DH215 Inflow Rates

Over 15 liters of brine were collected from DH215 over the 600 days of collection. This figure is a minimum figure and much more brine had been produced from the hole, but not collected and measured, prior to January 1985.

APPENDIX E

WIPP BSEP BRINE INFLOW DATA TABLES

TABLE E.1
Inflow Data for Hole A1X01 in Room A1

Date	Time	Liters Removed	Days Since 1/01/85	Cumulative Liters Collected	Liters per Day	Remarks
03/12/85	12:20	00.08	70.514	0.08	0.000	First time bailed.
03/20/85	13:30	00.38	78.562	0.46	0.047	Brine plus some muck.
03/26/85	11:25	00.23	84.476	0.69	0.039	Muck in hole. Valved leaked, some brine drained back down hole.

Subject: FW: Bulkhead Resistance

John,

To answer the questions you posed to me in the attached document:

1) The bulkheads used for the panel closure would have a smaller resistance value because the pressure drop is very small and the air flow is very small. The smaller range values are more apt to apply in the case of a panel closure bulkhead.
2) I am assuming that you are referencing the pressure drops in our E300 drift when you spoke of compiling the pressure drop for the "air exhaust entries adjacent to the panel entries for closed or inactive panels." E300 is our main exhaust drift. The high pressure drops that you saw were related to overcasts that were in place when the various test and balances of the vent system were performed. All overcasts have been removed, so you won't see the "high" values of 300-400 milli. In. in E300. In addition the floor has been trimmed, increasing the area of the drift which will help to reduce the pressure drop. For now I would expect to see pressure drops in the range of 100-150 milli. In. Over time as the entry area decreases with the salt convergence, the pressure drop will increase. I would think that 500 milli. In. would be very conservative for bounding purposes.
3) Our vent expert (sub-contractor) has told me that there is virtually no pressure drop in the closed panel. Air movement in and out of existing interim panel closure bulkheads is due to changes in barometric pressure. In reality, I have notice air movement when the pressure changes due to people opening and closing other bulkhead doors in the vicinity of the closed panels.
4) Yes, ventilation modeling of 9A and 10A has been performed with 9A as an active disposal panel and 10A under "construction" (mining). I don't have the model. I could ask our sub-contractor for the pressure drop info associated with the model if you would like to have it. Please let me know.

Subject: Bulkhead Resistance

Gentlemen:

I have attached a file with data about bulkhead resistance. We haven't spent time measuring resistance with and without bulkheads in drifts in the UG. The best that I could do was compare similar sized drifts with and without bulkheads in the model. I also used models from 2 different years to show the resistance of the same drift with and without a bulkhead. I'm not sure how you plan to use the bulkhead resistance number. If it is for a closed panel I would assume it is on the small side as there is neither a large flow nor a significant pressure drop across a closed panel. Let me know if there is anything more that I can do.

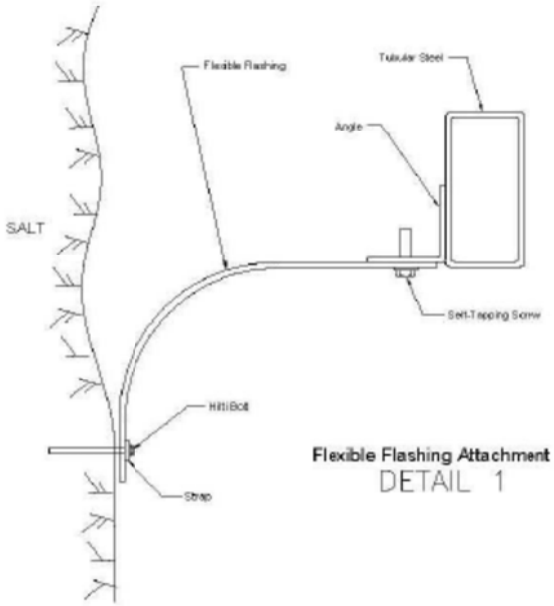
Ventilation Data

Thanks for the timely response in providing me with ventilation information. I have had the opportunity to compile and review the information. I have several questions.

Figure 1 shows a typical bulkhead comprised of sheet metal with a flexible flashing attachment to accommodate panel entry creep closure. This is the bulkhead that would be used in the Panel Closure Design emplaced in the intake and exhaust panel entries (Intake Entry: 20 ft. wide by 13 ft. high and Exhaust Entry: 14 ft. wide by 12 ft. high). You state that the resistance of large entry bulkheads is from 30 to 200 Practical Units (milli. In. w.g./kcfm^2). Smaller drifts have a higher air flow resistance. Some smaller drifts with bulkheads near the exhaust shaft have resistances as high as 2200 PU. Would the value of 2200 PU apply to a bulkhead comprised of reinforced sheet metal with flexible flashing installed in the intake and exhaust panel entries adjacent to closed or inactive panels?

I compiled the information concerning pressure drop (milli inches of water gage) for the air exhaust entries adjacent to the panel entries for closed or inactive panels. I obtain a range from 11 to 350 milli inches of water gage for the normal mode, and 25 to 460 milli inches of water gage for the full flow operating mode. The results reflect a broad range of pressure drops associated with changes in ventilation to the active room. I am currently thinking of using a value of 500 milli inches of water gage to conservatively bound the pressure drop for calculating the VOCs emissions rate. What do you think of this pressure drop for purposes of calculating air flow rates through closed or inactive panels? Would the value apply to future underground development? For example, if Panel 10 were being excavated, and Panel 9 were receiving waste, would the maximum value for pressure drop in the exhaust entries adjacent to closed/inactive panels be 500 milli inches of water gage? Have ventilation modeling studies been performed for the repository when Panel 10 is in development, and Panel 9 is receiving waste?



Flexible Flashing Attachment

Attention: Mr. Rick Chavez

RE: EARLY TIME GENERATION OF METHANE AND HYDROGEN IN FILLED PANELS AT THE WIPP

Dear Mr.Chavez:

This letter addresses expected maximum generation rates for methane and hydrogen in filled panels at the WIPP in response to some stakeholder concerns conveyed by the New Mexico Environment Department (NMED) during the November 22, 2006 conference call. Specifically it addresses the expected maximum concentrations of these gases five years after waste disposal in a panel is complete and ventilation to the panel is stopped. The generation rates and concentrations discussed here are taken from the existing application, supplemented as appropriate by additional publically available information.

Methane Concentrations

Analyses included in Appendix I1 of the WIPP Resource Conservation and Recovery Act Part B Permit Application, and in Appendix PCS of the 1996 Compliance Certification Application, show the potential build up of methane in the closed panels for gas generation rates of 0.01 and 0.1 moles per drum per year, assuming that 70% of the gas generated by microbial degradation is methane. Based on these calculations the concentration of methane for the 0.1 mole per drum per year generation rate will only reach 1% after 5 years, or 20% of the lower explosion limit (LEL) for methane in an atmospheric oxygen environment.

The 0.1 mole per drum per year rate is based on expected gas generation rates under inundated conditions where the rooms are filled with brine. It is not anticipated that these inundated conditions will exist in the first five years after shutting off ventilation to the panel, as evidenced by the lack of significant moisture in open rooms, or in rooms which have been shut-off from ventilation during panel filling. Expected generation rates under humid conditions are about one order of magnitude slower[1].

[1] US Department of Energy, Carlsbad Field Office, "Compliance Recertification Application, Appendix PA, Attachment PAR," March 2004

Gas generated by microbial action is expected to contain at least as much inflammable CO_2 as methane. A series of gas generation experiments under simulated WIPP conditions have been carried out at Brookhaven National Laboratory. These experiments subjected simulated waste materials to microbial degradation under simulated WIPP conditions. Early time data showed that after 853 days the major gas generated was CO_2, and no methane was detected[2]. Later results showed that after 1228 days methane had still not been produced. Minor amounts of methane were detected in some samples after 2718 days[3].

Based on this experimental evidence, and the use of a high generation rate in the calculations included in Attachment I1 of the permit application, it is apparent that the calculated value of 1% methane concentration after 5 years is extremely conservative.

Hydrogen Concentrations

Recently WTS has evaluated the potential for hydrogen generation by radiolysis, based on an analysis of the Panel 3 inventory, and generation rates obtained from head-space hydrogen data from actual containers prior to shipping[4]. These lead to a conservative estimate for the potential rate of hydrogen generation by radiolysis, and by extension to the maximum potential hydrogen concentrations in an unventilated panel. Using these rates, which equate to about 0.397 litres of hydrogen per drum per year, leads to a maximum potential hydrogen concentration from radiolysis of about 0.75% after 3 years, or 1.2% after 5 years. This is about 25% of the LEL for hydrogen in an atmospheric oxygen concentration. Hydrogen can also be generated by anoxic corrosion of steel in the wastes and the drums. However it is anticipated that anoxic conditions will take some time to develop and hydrogen is not generated by oxic corrosion. It should also be noted that rapid corrosion requires inundated conditions which, as discussed above, are also not expected to occur within the first five years...

Data on hydrogen concentrations for actual WIPP waste have been obtained by a series of gas generation experiments conducted at Argonne National Laboratories – West[5]. These experiments were run under inundated conditions, and under anoxic conditions established by pressurizing the containers with nitrogen. After about 5 ½ years the hydrogen concentrations in the containers were, less than 1% with the exception of one container which did show a value of 4.2%. It should be emphasized that these experiments were run under both anoxic and inundated conditions, which are not expected in the first five years after shutting off the ventilation to a panel.

It therefore has been determined that even under the most conservative assumptions of generation rates, and neglecting any affects of diffusion, the hydrogen concentrations after 5 years will be less than 1%, or 25 % of the LEL.

---

Conclusions

Existing calculational data and actual experimental results indicate that even under the most conservative assumptions methane and hydrogen concentrations in a filled and unventilated panel will not exceed between 1% and 1.2% for methane and hydrogen, respectively, in more than five years. These values represent 20% and 30% of the individual LELs, respectively, and 50% of the combined LEL.

Sincerely,

ABSTRACT

Modifications to the constitutive model used to describe the deformation of crushed salt are presented in this report. Two mechanisms—dislocation creep and grain boundary diffusional pressure solutioning—defined previously but used separately are combined to form the basis for the constitutive model governing the deformation of crushed salt. The constitutive model is generalized to represent three-dimensional states of stress. New creep consolidation tests are combined with an existing database that includes hydrostatic consolidation and shear consolidation tests conducted on Waste Isolation Pilot Plant and southeastern New Mexico salt to determine material parameters for the constitutive model. Nonlinear least-squares model fitting to data from the shear consolidation tests and a combination of the shear and hydrostatic consolidation tests produced two sets of material parameter values for the model. The change in material parameter values from test group to test group indicates the empirical nature of the model but demonstrates improvement over earlier work with the previous models. Key improvements are the ability to capture lateral strain reversal and better resolve parameter values. To demonstrate the predictive capability of the model, each parameter value set was used to predict each of the tests in the database. Based on the fitting statistics and the ability of the model to predict the test data, the model appears to capture the creep consolidation behavior of crushed salt quite well.

1.0 INTRODUCTION

1.1 Background

Construction of the Waste Isolation Pilot Plant (WIPP) was initiated by the U. S. Department of Energy (DOE) in 1981 to develop the technology for the safe management, storage, and disposal of transuranic (TRU) radioactive wastes generated by DOE defense programs. The WIPP, located in southeastern New Mexico at a depth of approximately 655 meters in bedded halites, consists of a series of underground shafts, drifts, panels, and disposal rooms. The WIPP may eventually become a repository for TRU wastes, provided the facility is demonstrated to be in compliance with the Environmental Protection Agency's requirements. If the compliance requirements are satisfied, each disposal room will be filled with containers holding TRU wastes of various forms. Ultimately a seal system designed to prevent water from entering the repository and to prevent gases and brines from migrating out of the repository must be in place.

Crushed salt has been proposed as a viable material for permanent sealing of WIPP underground openings. Crushed salt's desirable characteristics include chemical compatibility, eventual mechanical similarity with the host salt formation, and availability from the site excavation. Laboratory tests have shown that crushed salt achieves desirable permeability characteristics as consolidation increases the material density. In addition, voids and fractures close and heal in salt in response to applied loads. Reconsolidated crushed salt becomes a long-term seal component. Thus an understanding of the consolidation processes in crushed salt is fundamental to the design and analysis of a credible seal system that will provide confidence and establish regulatory compliance.

To gain an understanding of the crushed-salt consolidation processes, knowledge of the overall repository isolation system is required along with the interactions of key components such as host geology, brine, waste forms, generated gases, and seal elements. Representative and defensible material, flow, and chemical models are needed that describe the behavior of these components in the isolation system. The objective of this report is to update the mechanical material model appropriate for describing crushed-salt deformation. The WIPP crushed-salt material model or constitutive model, which relates stress and strain, predicts deformations and stresses in the underground sealing system. The magnitude of the stresses and strains throughout the isolation system determines the location and extent of the disturbed rock zone and serviceability of the seal components. Because crushed salt is an important seal material, its constitutive model must satisfy the needs of performance assessment and regulatory compliance.

1.2 Earlier Work

Crushed salt has received international attention over the past 20 years, primarily within a repository setting. An earlier study (Callahan et al., 1995) searched the literature for constitutive models developed for crushed salt. Ten models, based to varying degrees on phenomenology, micromechanics, or empiricism, were found. Three of these models were selected for detailed examination. The three models are those attributable to Sjaardema-Krieg (1987), Zeuch and Holcomb (Zeuch, 1990), and Spiers and coworkers (Spiers and Brzesowsky, 1993). These constitutive models were developed to reproduce hydrostatic (isostatic) consolidation laboratory tests and include only the volumetric strain component. The Sjaardema and Krieg model is empirical and was retained for comparative purposes because it was used in the past for calculation of crushed-salt problems at the WIPP. The Zeuch and Holcomb model was constructed for nominally dry crushed salt and is based on the isostatic hot-pressing models combined with dislocation creep. The Spiers and coworkers model was formulated for wet crushed-salt aggregates and is based on grain boundary diffusional pressure solution processes. These three models were modified to include effects thought to be important for WIPP salt. A flow potential and associated three-dimensional generalization were developed for the models so that they could operate over a wide range of stress triaxialities (ratio of mean stress to effective or deviatoric stress) and be applicable to arbitrary states of stress. A database of applicable crushed-salt laboratory tests was constructed comprising 40 hydrostatic consolidation tests and 10 shear consolidation tests. The experimental data were fit to determine values for the material parameters associated with each of the models. The hydrostatic and shear consolidation tests and their combination were fit separately so that three different parameter value sets were obtained. If a constitutive model was representative and the data were unbiased, the change in parameter values among fits should have been minimal. However, in the earlier study, the change in the parameter values was significant. These three models performed about equally well, with the modified Spiers model exhibiting moderate superiority.

Following completion of the earlier study for the evaluation of potential constitutive models for crushed salt (Callahan et al., 1995), the constitutive model formulation was found to be inadequate at high fractional densities. In addition, because of the heavy bias in the database toward hydrostatic consolidation tests, along with the fact that none of the shear consolidation tests reached high enough fractional densities to exhibit positive lateral strains, the constants associated with the flow potential made it impossible for the simulated crushed salt to move toward a volume-preserving flow (as is exhibited by intact salt) as the fractional density approached one. Most of the test data in the crushed-salt laboratory database exhibit a positive lateral-to-axial strain rate ratio, whereas the lateral-to-axial strain rate ratio is negative for a triaxial test conducted on intact salt. However, as the crushed salt consolidates, at some density

level the lateral deformation must change direction (i.e., cease to move inward and begin to move outward as is observed for the intact salt tests). In addition to being a function of the density, this change in lateral strain direction is also, undoubtedly, a function of the state of stress. Having identified these shortcomings in the crushed-salt model, two additional shear consolidation tests were conducted to expand the database at higher fractional densities near 0.8 (RE/SPEC Inc., 1996). The functional form of the flow potential for the models was modified, and the models were refit to the database. This study, discussed in RE/SPEC Inc. (1996) and Callahan et al. (1996), resulted in satisfactory model predictions over a wide range of fractional densities and stress triaxialities. However, the governing deformation mechanisms for crushed salt with varying degrees of added moisture were contained independently in two separate models.

Thus a goal of the present study was to incorporate the governing mechanisms into a single model. In addition, four new laboratory shear consolidation experiments were conducted with fractional densities near the initial fractional density expected in the dynamically compacted crushed-salt seal (approximately 0.9). These tests allow the database to be expanded into fractional density ranges previously untested and provide information on the crushed-salt flow behavior as its density increases. These tests were added to the experimental database, which was fit to obtain material parameter values for the updated crushed-salt constitutive model. The sign convention used throughout this report is tension positive.

1.3 Report Organization

This report focuses on the mechanical constitutive behavior of crushed salt. Chapter 2 describes the constitutive model, provides the three-dimensional generalization of the model, and reduces the general model form to specific types of laboratory tests. Chapter 3 summarizes the crushed-salt experimental database along with recently completed tests used to fit the constitutive model and determine its material constants. Chapter 4 describes the nonlinear least-squares fitting procedure used to fit the constitutive model to the experimental database and presents the resulting parameter values. Chapter 5 compares the crushed model to other models for porous materials available in the literature. Chapter 6 discusses modifications to the moisture function and flow potential, which were subsequently not used in the final form of the crushed-salt model. The report is concluded with a summary and recommendations in Chapter 7, followed by a list of referenced material, a bibliography, and three appendices.

2.0 CRUSHED-SALT CONSTITUTIVE MODEL

This chapter presents the crushed-salt deformation mechanisms, the general form for the crushed-salt constitutive model, development of the three-dimensional generalization for the creep consolidation model, and reduction of the constitutive model to the form necessary to fit the laboratory data and evaluate the material model parameters.

2.1 Crushed-Salt Deformation Mechanisms

Multiple deformation mechanisms control the densification of crushed salt for the seal emplacement processes and range of conditions expected at the WIPP, where crushed salt is planned as a major sealing component in the shafts. During emplacement in the shafts, crushed salt will be dynamically compacted with small amounts of added moisture (less than 2 percent by weight) to a fractional density of about 0.9. During dynamic compaction, the densification of the crushed salt will occur through particle rearrangement, cataclasis, and plastic yield. These *instantaneous* processes provide a dense, locked-up aggregate. Further densification occurs over time through compactional loading on the crushed-salt column caused by creep of the host salt formation and inward movement of the shaft walls. As crushed salt is loaded, the principal densification mechanisms include dislocation creep and fluid-phase diffusional creep (grain boundary diffusional pressure solutioning). Without the added moisture during construction of the crushed-salt seal component, the importance of the diffusional creep mechanism would diminish. The model that defines the dislocation creep of intact salt is defined in terms of three dislocation mechanisms involving dislocation climb, an undefined (but experimentally and empirically well established) mechanism, and dislocation glide (Munson et al., 1989). The presence of the liquid phase leads to the additional deformational processes characterized by stress-induced dissolution, diffusion, and precipitation. The diffusional creep rate is controlled by the slowest of these serial processes. The grain boundary diffusional pressure solution mechanism dramatically enhances the densification rate in crushed salt (Spiers and Schutjens, 1990).

The idea of pressure solutioning as a deformation mechanism has been around for over 100 years but has only been studied in detail for application to geologic systems during the last 25 years. The fundamental process is characterized by a liquid phase occurring perhaps as a thin liquid film at grain interfaces. The diffusive mass transfer process has been called fluid-phase diffusional creep, solution-precipitation creep, pressure solution, and grain boundary diffusional pressure solution. The mechanism is analogous to diffusional creep (Coble creep) where matter is transported distances on the order of the grain size and controlled by diffusion of atoms

through the grain interfaces. In the solution-precipitation creep process, matter transport is characterized by diffusion through the fluid at the grain interfaces. A significant difference between the two creep processes is that solution-precipitation creep occurs at much lower temperatures than the classical diffusional creep.

The constitutive model developed for crushed salt discussed in the following sections incorporates the dislocation creep and pressure solutioning mechanisms.

2.2 General Form for the Crushed-Salt Constitutive Model

The total strain rate for the crushed-salt constitutive model is assumed to consist of two components. The components include nonlinear elastic $\left(\dot{\epsilon}_{ij}^{e} \right)$ and creep consolidation $\left(\dot{\epsilon}_{ij}^{c} \right)$ contributions, and the total strain rate is written as:

$$\dot{\epsilon}_{ij} = \dot{\epsilon}_{ij}^{e} + \dot{\epsilon}_{ij}^{c} \tag{2-1}$$

When the strains become finite, the expressions for strain rate should be interpreted as the rate of deformation. Both the nonlinear elastic and creep consolidation portions of the model describe the material behavior in bulk (volumetric) and in shear (deviatoric). However, as shown later, when the fractional density approaches unity, the creep consolidation portion of the model only describes deviatoric material behavior and is, in fact, the creep deformation model used for intact salt. The nonlinear elastic portion of the model presented by Callahan et al. (1995) has not changed and will not be presented again. The creep consolidation portion of the model is presented along with its evolution to the intact salt model.

2.3 Creep Consolidation Model

The creep consolidation model is of primary concern in this study, and thus this section is divided into subsections that address important issues regarding the creep consolidation portion of the crushed-salt consolidation model. Typically equations proposed to describe the behavior of a particular material are written in one-dimensional form or as scalar relationships. To be useful in numerical analyses and applicable to a variety of laboratory experiments with different load paths, any constitutive model must be generalized to include three-dimensional states of stress. The first subsection presents the generalization of the creep consolidation model. The next subsection collapses or reduces the generalized form of the creep consolidation equation to specific laboratory test conditions, which yields simplified forms that can be used in fitting the model to the experimental database. The third subsection presents the effective strain rate model

forms that represent the two mechanisms associated with the crushed-salt creep consolidation component of the constitutive model.

2.3.1 Creep Consolidation Model Generalization

To develop the creep consolidation constitutive equation for crushed salt, two operative deformation mechanisms are assumed: dislocation creep and grain boundary diffusional pressure solutioning. Dislocation creep is the governing mechanism for deformation of intact salt (e.g., Munson et al., 1989). The stress-induced dissolution and precipitation process or simply pressure solutioning is an operative mechanism when small quantities of water (brine) are contained in the aggregate (e.g., Spiers and Brzesowsky, 1993). As discussed by Stocker and Ashby (1973) and Helle et al. (1985), the creep and diffusional mechanisms are independent and additive. From the application of thermodynamic concepts, the three-dimensional generalization of kinetic equations is given by Fossum et al. (1988). Following this approach, the generalized average kinetic equation for the creep consolidation inelastic flow of crushed salt can be written as:

$$\dot{\epsilon}^{c}_{ij} = \left[\dot{\epsilon}^{d}_{eq}\left(\sigma^{f}_{eq}\right) + \dot{\epsilon}^{w}_{eq}\left(\sigma^{f}_{eq}\right) \right] \frac{\partial \sigma_{eq}}{\partial \sigma_{ij}} \tag{2-2}$$

where $\dot{\epsilon}^{c}_{ij}$ is the inelastic strain rate tensor and σ^{f}_{eq} is an equivalent stress measure. The equivalent inelastic strain rate measures for dislocation creep $\left(\dot{\epsilon}^{d}_{eq}\right)$ and pressure solutioning $\left(\dot{\epsilon}^{w}_{eq}\right)$ are written as functions of the equivalent stress measure. For use in the flow potential, another equivalent stress measure, σ_{eq}, is used to provide a nonassociative type of formulation that provides flexibility in governing the magnitude of the volumetric behavior.

Motivation for selection of the equivalent stress measures comes from laboratory experiments reported in previous work (Callahan et al., 1995; 1996). Tests on crushed-salt specimens exhibit a strong dependence on the pressure (mean stress) applied to the specimens. Shear consolidation experiments also exhibit differing behavior depending on the magnitude of applied stress difference. Thus the appropriate stress measure should include both mean and deviatoric stress dependencies. Laboratory tests on intact salt specimens show little dependence on moderate mean stress levels (< –2 MPa), and typically the deformation of intact salt is described as a volume-preserving process. Therefore one would expect the mean stress influence to decrease as the crushed salt approaches full consolidation. Perhaps most importantly, in a typical triaxial test, the effective stress measure describing the potential surface must provide a reversal in lateral strain rate as the fractional density approaches one. This condition is a natural consequence at low stress triaxialities (ratio of mean to deviatoric stress) because porous crushed salt decreases in volume but intact salt inelastic deformation is isochoric (volume preserving) unless damage is occurring.

Sofronis and McMeeking (1992) discuss the ratio of mean stress to deviatoric stress or stress triaxiality as considered by a number of researchers. They discuss investigations of stress triaxiality over ranges of fractional density, which are pertinent to the crushed-salt investigations. Crushed salt emplaced in the underground workings and shafts at the WIPP will experience moderate levels of stress triaxiality. Models for hot isostatic pressing (HIPing) of powders presented by Helle et al. (1985), which also provide the basis for Zeuch's (1990) crushed-salt model, have an infinite ratio of mean stress to shear stress. Therefore, Callahan et al. (1995) and RE/SPEC Inc. (1996) modified Zeuch's model for applicability in the moderate stress triaxiality ranges. Duva and Hutchinson (1984) developed a constitutive model for power-law creep of an incompressible matrix material containing a dilute concentration of spherical voids. Their model is thought to be valid for moderate stress triaxialities with fractional densities greater than 0.9. However, when the triaxiality is high, the model is only valid for porosities less than 1 percent. Duva (1986) modified the original model of Duva and Hutchinson (1984) so that the accuracy was improved at higher porosities for moderate triaxialities, but the model is still unsatisfactory for high triaxial stress states except when the porosity is low. Cocks (1989) states that the surface of constant energy dissipation rate (i.e., the creep potential surface) for a creeping solid is a function of stress and void volume fraction only, and independent of material parameters apart from a weak dependence on the creep stress exponent. Cocks' conclusion is based on a lower bound analysis for an isolated spherical void. Cocks' constitutive law for power-law creeping materials is not accurate for low porosities when the stress is predominantly hydrostatic, but performs better at higher void volume fractions. In contrast to the constitutive laws that contain a range of stress triaxialities, the models of Wilkinson and Ashby (1975), Arzt et al. (1983), and Helle et al. (1985) are valid only for states of pure hydrostatic stress; however, the models are probably more accurate over a larger range of fractional densities for these stress conditions. Sofronis and McMeeking (1992) developed a creep potential for power-law materials based on finite element calculations of spherical unit cells with a central spherical hole to represent the voids. They found that the dominant component, whether dilational or deviatoric, is always well represented. Comparisons with uniaxial compression experimental data from other sources showed that the ratio of the lateral-to-axial strain rates was predicted fairly accurately, although the strain rate magnitudes were not.

Crushed salt emplaced at the WIPP will experience broad ranges of fractional density and stress triaxiality over the life of the repository. As discussed for the earlier studies, little success has been achieved in a single constitutive model's ability to cover all these required conditions. Fortunately the crushed salt emplaced in the shaft will be dynamically compacted to an initial fractional density of about 0.9. This limits the accuracy required in the crushed-salt constitutive model to fractional densities between 0.9 and 1.0. However, much of the existing crushed-salt laboratory data have been generated for fractional densities less than 0.9. In our first study (Callahan et al., 1995), the most promising existing models for crushed salt were identified and generalized for arbitrary states of stress. However, the large number of hydrostatic consolidation test results in the database used to evaluate material parameters resulted in a model that was invalid at low stress triaxialities. The second study (RE/SPEC Inc., 1996; Callahan et al., 1996) corrected this problem by designing and adding two tests that expanded the experimental results

into a previously unrepresented region of material behavior, modifying the functional form of the flow potential, and independently fitting the flow potential to the strain rates to determine the parameter values. In the present study, the two identified operative mechanisms are combined in the constitutive model to characterize the consolidation of crushed salt.

With these considerations, the equivalent stress measures are homogeneous of degree one in terms of stress and are given by:

$$\sigma_{eq}^{f} = \left[\eta_0 \Omega_f^{\eta_1} \sigma_m^2 + \eta_2 \left(\frac{2 - D}{D} \right)^{\frac{2n_f}{n_f + 1}} (\sigma_1 - \sigma_3)^2 \right]^{1/2}$$

$$\sigma_{eq} = \left[\kappa_0 \Omega^{\kappa_1} \sigma_m^2 + \kappa_2 \left(\frac{2 - D}{D} \right)^{\frac{2n}{n + 1}} (\sigma_1 - \sigma_3)^2 \right]^{1/2} \qquad (2\text{-}3)$$

where:

$$\Omega_f = \left[\frac{(1 - D)\, n_f}{\left[1 - (1 - D)^{1/n_f} \right]^{n_f}} \right]^{\frac{2}{n_f + 1}} \qquad (2\text{-}4)$$

$$\Omega = \left[\frac{\left(1 - D_v\right) n}{\left[1 - \left(1 - D_v\right)^{1/n} \right]^{n}} \right]^{\frac{2}{n + 1}} \qquad (2\text{-}5)$$

$$D_v = \begin{cases} D_t & D \le D_t \\ D & D > D_t \end{cases} \qquad (2\text{-}6)$$

D = current fractional density

σ_m = mean stress = $\frac{\sigma_{kk}}{3}$

σ_3 = minimum principal stress

σ_1 = maximum principal stress

η_0, η_1, η_2, κ_0, κ_1, κ_2, n_f, n, and D_t = material parameters.

The fractional density relationships given in Equations 2-4 and 2-5 are similar to the densification relationship derived by Wilkinson and Ashby (1975) for an isolated spherical void

in a power-law creeping material when the fractional density is greater than 0.9. Their analytical solution to this problem showed that the macroscopic densification rate was proportional to the fractional density relationship written as:

$$\frac{\dot{D}}{D} \alpha \frac{(1 - D)}{\left[1 - (1 - D)^{1/n}\right]^n} \tag{2-7}$$

where n is the stress exponent for the power-law material. The functional form for the fractional density relationship is carried through in the models presented by Arzt et al. (1983), Helle et al. (1985), and Zeuch (1990). Sofronis and McMeeking (1992) adopted a similar form for their elliptic form of the potential function for power-law creep of a material containing spherical voids. Kwon and Kim (1996a; 1996b) used the potential functions derived by Kuhn and McMeeking (1992) and Sofronis and McMeeking (1992) to develop models for densification of alumina powder.

As crushed salt approaches full consolidation (i.e., D → 1), Ω_f and Ω approach zero and the dependence on mean stress diminishes, which is required for an incompressible material matrix. The fractional density functions multiplying the deviatoric terms in Equation 2-3 are taken from Sofronis and McMeeking (1992). They state that, under purely deviatoric situations, this term exceeds the lower bound developed by Ponte Casteneda and Willis (1988) for large fractional densities but provides a good approximation to the results of Duva and Hutchinson (1984). Thus, letting $D = 1$, Equation 2-3 becomes:

$$\begin{aligned} \sigma_{eq}^{f} &= \sqrt{\eta_2}\left(\sigma_1 - \sigma_3\right) \\ \sigma_{eq} &= \sqrt{\kappa_2}\left(\sigma_1 - \sigma_3\right) \end{aligned} \tag{2-8}$$

Twice the maximum shear stress or Tresca equivalent stress is used in the equivalent stress measures to describe the shear behavior, as is common for intact salt, and is given by:

$$\sigma_1 - \sigma_3 = 2\cos\psi\sqrt{J_2} \tag{2-9}$$

with the second and third invariants of the deviator stress (J_2 and J_3) defined by:

$$\begin{aligned} J_2 &= \frac{1}{2} s_{ij} s_{ji} \\ J_3 &= \frac{1}{3} s_{ij} s_{jk} s_{ki} \end{aligned} \tag{2-10}$$

where the Lode angle (ψ), which is a convenient alternative invariant to J_3, is given by:

$$\psi = \frac{1}{3}\sin^{-1}\left(\frac{-3\sqrt{3}J_3}{2J_2^{3/2}}\right), \left(-\frac{\pi}{6} \le \psi \le \frac{\pi}{6}\right) \tag{2-11}$$

The partial derivative given in Equation 2-2 may be determined using the chain rule as:

$$\frac{\partial \sigma_{eq}}{\partial \sigma_{ij}} = \frac{\partial \sigma_{eq}}{\partial \sigma_m}\frac{\partial \sigma_m}{\partial \sigma_{ij}} + \frac{\partial \sigma_{eq}}{\partial J_2}\frac{\partial J_2}{\partial \sigma_{ij}} + \frac{\partial \sigma_{eq}}{\partial \psi}\frac{\partial \psi}{\partial J_3}\frac{\partial J_3}{\partial \sigma_{ij}} \tag{2-12}$$

The derivatives of the invariants in Equation 2-12 are the same regardless of the invariant stress and strain measures selected. These derivatives are:

$$\begin{aligned}
\frac{\partial \sigma_m}{\partial \sigma_{ij}} &= \frac{\delta_{ij}}{3} \\
\frac{\partial J_2}{\partial \sigma_{ij}} &= s_{ij} \\
\frac{\partial \psi}{\partial J_3}\frac{\partial J_3}{\partial \sigma_{ij}} &= -\frac{\sqrt{3}}{2J_2^{3/2}\cos 3\psi}\, t_{ij}
\end{aligned} \tag{2-13}$$

where:

δ_{ij} = Kronecker delta

$$t_{ij} = s_{ip}s_{pj} - \frac{2}{3}J_2\delta_{ij}$$

Equation 2-12, defining the flow potential, also requires the partial derivatives of the equivalent stress measure (Equation 2-3) with respect to stress. Performing the required differentiation yields:

$$\frac{\partial \sigma_{eq}}{\partial \sigma_m} = \frac{\kappa_0 \Omega^{\kappa_1} \sigma_m}{\sigma_{eq}}$$

$$\frac{\partial \sigma_{eq}}{\partial J_2} = \frac{4 \kappa_2}{\sigma_{eq}} \left(\frac{2 - D}{D} \right)^{\frac{2n}{n+1}} \frac{\cos\psi \cos 2\psi}{\cos 3\psi} \tag{2-14}$$

$$\frac{\partial \sigma_{eq}}{\partial \psi} = -\frac{4 \kappa_2}{\sigma_{eq}} \left(\frac{2 - D}{D} \right)^{\frac{2n}{n+1}} \cos\psi \sin\psi J_2$$

Substituting Equations 2-12, 2-13, and 2-14 into Equation 2-2 provides the tensorial strain rate components for the creep consolidation portion of the crushed-salt model, which is given by:

$$\dot{\epsilon}_{ij}^{c} = \frac{\dot{\epsilon}_{eq}^{d} + \dot{\epsilon}_{eq}^{w}}{\sigma_{eq}} \left\{ \frac{\kappa_0 \Omega^{\kappa_1} \sigma_m}{3} \delta_{ij} + \kappa_2 \left(\frac{2 - D}{D} \right)^{\frac{2n}{n+1}} 2\sqrt{J_2} \cos\psi \right.$$

$$\left. \left(\left[\frac{\cos 2\psi}{\cos 3\psi} \right] \frac{s_{ij}}{\sqrt{J_2}} + \left[\frac{\sqrt{3} \sin\psi}{J_2 \cos 3\psi} \right] t_{ij} \right) \right\} \tag{2-15}$$

Equation 2-15 is seen to be undefined as the Lode angle approaches $\pm\pi/6$. In other words, the flow potential forms corners at $\psi = \pm\pi/6$, and the direction of straining is not unique. To eliminate this problem computationally, the flow potentials on either side of the corner are averaged, which produces an indeterminant form that is examined in the limit as $\psi \rightarrow \pm\pi/6$. Performing this limiting operation, Equation 2-15 becomes:

$$\dot{\epsilon}_{ij}^{c} = \frac{\dot{\epsilon}_{eq}^{d} + \dot{\epsilon}_{eq}^{w}}{\sigma_{eq}} \left\{ \frac{\kappa_0 \Omega^{\kappa_1} \sigma_m}{3} \delta_{ij} + \kappa_2 \left(\frac{2 - D}{D} \right)^{\frac{2n}{n+1}} \sqrt{3 J_2} \right.$$

$$\left. \left(\frac{s_{ij}}{\sqrt{3 J_2}} \mp \frac{t_{ij}}{2 J_2} \right) \right\} \tag{2-16}$$

The flow potential contains five material parameters (κ_0, κ_1, κ_2, D_i, and n) that need to be determined from laboratory experiments. To complete the crushed-salt creep consolidation

description, the kinetic equations describing dislocation creep and pressure solutioning in crushed salt need to be defined. In general, these kinetic equations could be a form of any specific model that captures the desired characteristics of the material deformation. Discussion of these specific forms is included in Sections 2.3.3 and 2.3.4 following presentation of other general considerations for the crushed-salt consolidation model.

2.3.2 Evaluation of Laboratory Test Equation Forms

To compare the crushed-salt constitutive equations to laboratory experiments, one needs to reduce the equations to the applicable test conditions. In particular, tests of interest are the hydrostatic compression, triaxial compression, and extension tests. To derive these forms, one simply needs to substitute the applicable test conditions into the constitutive equations and reduce them to their simplest forms. The hydrostatic compression test conditions can be easily obtained from the triaxial compression test conditions by letting the stress difference ($\Delta\sigma = \sqrt{3J_2}$) equal zero. The directions $\{zz, yy, xx\}$ are taken as $\{33, 22, 11\}$, and the $\{zz\}$ direction is taken to be the axial direction. For simplicity, the following variables are defined:

$$\alpha = \frac{\kappa_0 \Omega^{\kappa_1} \sigma_m}{3}$$
$$\beta = \kappa_2 \left[\frac{2 - D}{D}\right]^{\frac{2n}{n+1}} \sqrt{3 J_2} \qquad (2\text{-}17)$$

Fitting of the constitutive model can be conveniently separated into two separate stages. The first step includes fitting the ratio of the lateral strain rate to the axial strain rate defined as **R** and written as:

$$\mathbf{R} = \frac{\dot{\epsilon}_l^c}{\dot{\epsilon}_a^c} \qquad (2\text{-}18)$$

Fitting the strain rate ratio allows the parameter values associated with the flow potential (i.e., α and β in Equation 2-17) to be determined independently of the other material parameter values. Obviously the test data must contain experiments where the stress triaxiality conditions lie between zero and infinity for the fitting to be successful. This can be accomplished with the shear consolidation tests.

Reduction to Triaxial Compression Creep Test ($\psi = \pi/6$)

The triaxial compression creep test is prescribed by controlling a constant stress state defined by $\sigma_{zz} < \sigma_{xx} = \sigma_{yy}$. Under these stress conditions, the stress measures included in Equation 2-16 reduce to:

$$\sqrt{3J_2} = \Delta\sigma = \sigma_1 - \sigma_3$$

$$J_2 = \frac{\Delta\sigma^2}{3}$$

$$s_{zz} = \sigma_{zz} - \sigma_m = -\frac{2}{3}\Delta\sigma$$

$$s_{xx} = s_{yy} = \sigma_{xx} - \sigma_m = \frac{\Delta\sigma}{3} \qquad (2\text{-}19)$$

$$t_{zz} = s_{zz}^2 + s_{zx}^2 + s_{zy}^2 - \frac{2}{3}J_2 = \frac{2\Delta\sigma^2}{9}$$

$$t_{xx} = t_{yy} = s_{xx}^2 + s_{xy}^2 + s_{xz}^2 - \frac{2}{3}J_2 = -\frac{\Delta\sigma^2}{9}$$

$$\left(\frac{s_{zz}}{\sqrt{3J_2}} - \frac{t_{zz}}{2J_2}\right) = -1$$

$$\left(\frac{s_{xx}}{\sqrt{3J_2}} - \frac{t_{xx}}{2J_2}\right) = \frac{1}{2}$$

Therefore the axial (*a*), lateral (*l*), and volumetric (*v*) strain components and strain rate ratio for the creep consolidation portion of the model may be determined from Equations 2-16, 2-17, 2-18, and 2-19 as:

$$\dot{\epsilon}_a^c = [\alpha - \beta]\frac{\dot{\epsilon}_{eq}^d + \dot{\epsilon}_{eq}^w}{\sigma_{eq}}$$

$$\dot{\epsilon}_l^c = \left[\alpha + \frac{\beta}{2}\right]\frac{\dot{\epsilon}_{eq}^d + \dot{\epsilon}_{eq}^w}{\sigma_{eq}} \qquad (2\text{-}20)$$

$$\dot{\epsilon}_v^c = 3\,\alpha\,\frac{\dot{\epsilon}_{eq}^d + \dot{\epsilon}_{eq}^w}{\sigma_{eq}}$$

$$\mathbf{R} = \frac{\alpha + \frac{\beta}{2}}{\alpha - \beta}$$

Reduction to Triaxial Extension Test ($\psi = -\pi/6$)

The triaxial extension creep test is prescribed by controlling a constant stress state defined by $\sigma_{zz} > \sigma_{xx} = \sigma_{yy}$. Under these stress conditions, the stress measures in Equation 2-16 reduce to:

$$\sqrt{3J_2} = \Delta\sigma = \sigma_1 - \sigma_3$$

$$J_2 = \frac{\Delta\sigma^2}{3}$$

$$s_{zz} = \sigma_{zz} - \sigma_m = \frac{2}{3}\Delta\sigma \qquad (2\text{-}21)$$

$$s_{xx} = s_{yy} = \sigma_{xx} - \sigma_m = -\frac{\Delta\sigma}{3}$$

$$t_{zz} = s_{zz}^2 + s_{zx}^2 + s_{zy}^2 - \frac{2}{3}J_2 = \frac{2\Delta\sigma^2}{9}$$

$$t_{xx} = t_{yy} = s_{xx}^2 + s_{xy}^2 + s_{xz}^2 - \frac{2}{3}J_2 = -\frac{\Delta\sigma^2}{9}$$

$$\left(\frac{s_{zz}}{\sqrt{3J_2}} + \frac{t_{zz}}{2J_2}\right) = 1$$

$$\left(\frac{s_{xx}}{\sqrt{3J_2}} + \frac{t_{xx}}{2J_2}\right) = -\frac{1}{2}$$

Therefore the axial (a), lateral (l), and volumetric (v) strain components and strain rate ratio for the creep consolidation portion of the model may be determined from Equations 2-16, 2-17, 2-18, and 2-21 as:

$$\dot{\epsilon}_a^c = [\alpha + \beta] \frac{\dot{\epsilon}_{eq}^d + \dot{\epsilon}_{eq}^w}{\sigma_{eq}}$$

$$\dot{\epsilon}_l^c = \left[\alpha - \frac{\beta}{2}\right] \frac{\dot{\epsilon}_{eq}^d + \dot{\epsilon}_{eq}^w}{\sigma_{eq}} \qquad (2\text{-}22)$$

$$\dot{\epsilon}_v^c = 3\,\alpha \frac{\dot{\epsilon}_{eq}^d + \dot{\epsilon}_{eq}^w}{\sigma_{eq}}$$

$$\mathbf{R} = \frac{\alpha - \frac{\beta}{2}}{\alpha + \beta}$$

2.3.3 Equivalent Inelastic Strain Rate Form for Dislocation Creep

Dislocation creep of intact salt has been characterized by the Multimechanism Deformation (M-D) model (Munson, 1979; Munson and Dawson, 1979; Munson et al., 1989). Thus the equivalent inelastic strain rate measure for the dislocation creep portion of the crushed-salt model is taken to be the M-D material model. The model is written as:

$$\dot{\epsilon}_{eq}^d = F\,\dot{\epsilon}_s \qquad (2\text{-}23)$$

where $\dot{\epsilon}_{eq}^d$ is the kinetic equation and $\dot{\epsilon}_s$ is the steady-state strain rate. The transient function F consists of three branches — a work-hardening branch, an equilibrium branch, and a recovery branch — and is written in that order as:

$$F = \begin{cases} \exp\left[\Delta\left(1 - \dfrac{\zeta}{\epsilon_t^f}\right)^2\right] & \zeta < \epsilon_t^f \\ 1 & \zeta = \epsilon_t^f \\ \exp\left[-\delta\left(1 - \dfrac{\zeta}{\epsilon_t^f}\right)^2\right] & \zeta > \epsilon_t^f \end{cases} \qquad (2\text{-}24)$$

Δ and δ are the work-hardening and recovery parameters, respectively, and ϵ_t^f is the transient strain rate limit. The internal variable ζ is governed by the evolution equation:

$$\dot{\zeta} = (F - 1)\,\dot{\epsilon}_s \tag{2-27}$$

and the transient strain limit is given by:

$$\epsilon_t^f = K_0 e^{cT}\left(\frac{\sigma_{eq}^f}{\mu}\right)^m \tag{2-28}$$

where:

T = temperature

μ = shear modulus

K_0, c, and m = material parameters.

The work-hardening parameter is defined as a function of stress:

$$\Delta = \alpha + \beta \log\left(\frac{\sigma_{eq}^f}{\mu}\right) \tag{2-28}$$

where α and β are material parameters. Because of insufficient data, the recovery parameter (δ) is taken to be a constant. However, functional forms similar to Equation 2-27 are sometimes used for recovery, viz:

$$\delta = \alpha_r + \beta_r \log\left(\frac{\sigma_{eq}^f}{\mu}\right) \tag{2-28}$$

where α_r and β_r are material parameters.

The steady-state strain rate is the sum of the three individual strain rate mechanisms acting together:

$$\dot{\epsilon}_s = \sum_{i=1}^{3} \dot{\epsilon}_{s_i} \tag{2-29}$$

The three contributing mechanisms — dislocation climb, an undefined mechanism, and slip — are written respectively as:

$$\dot{\epsilon}_{s_1} = A_1 \left(\frac{\sigma_{eq}^f}{\mu} \right)^{n_1} \exp\left(-\frac{Q_1}{RT} \right) \tag{2-30}$$

$$\dot{\epsilon}_{s_2} = A_2 \left(\frac{\sigma_{eq}^f}{\mu} \right)^{n_2} \exp\left(-\frac{Q_2}{RT} \right) \tag{2-31}$$

$$\dot{\epsilon}_{s_3} = \left(B_1 e^{-Q_1/RT} + B_2 e^{-Q_2/RT} \right) \sinh\left[q \left(\frac{\sigma_{eq}^f - \sigma_0}{\mu} \right) \right] H\left(\sigma_{eq}^f - \sigma_0 \right) \tag{2-32}$$

where:

μ = shear modulus

q = activation volume

A_1, A_2, B_1, B_2, n_1, n_2, Q_1, Q_2, and σ_0 = experimental constants

R = universal gas constant

$H(.)$ = Heaviside step function.

2.3.4 Equivalent Inelastic Strain Rate Form for Pressure Solutioning

Spiers and Brzesowsky (1993) presented a grain boundary diffusional pressure solution model for wet crushed salt as:

$$\dot{\epsilon}_v^c = A V_m \frac{\exp\left(-\frac{Q_s}{RT}\right)}{T} \left(\frac{\sigma_m - P}{d^p}\right) \left(\frac{\left(1 + \epsilon_v\right)^{r_3}}{\left|\epsilon_v\right|^{r_4}}\right) \Gamma \tag{2-33}$$

where A, V_m, Q_s, r_3, and r_4 are material constants; T is absolute temperature; R is the universal gas constant; d is the grain size; and P is the pore pressure. The model consists of two functional forms, one for small strain and one for large strain, which are invoked depending on the prescribed value for Γ given as:

$$\Gamma = \begin{cases} 1 & \text{small strain } \left(\epsilon_v > -15\%\right) \\ \left[\frac{\epsilon_v + \phi_0}{\phi_0\left(\epsilon_v + 1\right)}\right]^{n_s} & \text{large strain } \left(\epsilon_v < -15\%\right) \end{cases} \tag{2-34}$$

where ϕ_0 is the initial porosity and n_s is a material parameter. Spiers and Brzesowsky (1993) developed the function Γ to account for increasing surface contact (increasing area and decreasing stress) as the strains become large. This geometrically interpreted variable serves to decrease the magnitude of the driving force.

The Spiers and Brzesowsky model is used to represent the equivalent inelastic strain rate form for pressure solutioning with modifications. The functional form given in Equation 2-33 is modified by changing the stress-dependent term (using the equivalent stress measure defined in Equation 2-3) and adding the effect of moisture (w is the moisture fraction by weight). The moisture function (simply w raised to a power, a) eliminates any strain rate contribution to the crushed-salt consolidation model when moisture content is zero. In addition, the pore pressure dependency (parameter P in Equation 2-33) has been dropped from the model because insufficient test data are available to include pore pressure as a state variable. With these modifications, the modified Spiers model used to define the kinetic equation becomes:

$$\dot{\epsilon}_{eq}^w = \frac{r_1 w^a}{d^p} \frac{e^{-\frac{Q_s}{RT}}}{T} \left(\frac{\left(1 + \epsilon_v\right)^{r_3}}{\left|\epsilon_v\right|^{r_4}}\right) \Gamma \sigma_{eq}^f \tag{2-35}$$

Notice that material constants A and V_m appearing in Equation 2-33 have been combined into one parameter, r_1, in Equation 2-35 and defined as:

$$r_1 = AV_m = \text{material constant} \left[\frac{\text{m}^p \cdot K}{\text{MPa} \cdot \text{s}}\right] \tag{2-36}$$

A problem is evident in the Spiers model at time zero. Equation 2-35 can be indeterminate because when $\sigma_{eq}^f = 0$ the initial volumetric strain is zero. To eliminate this problem during computations, some initial value must be assumed for the volumetric strain. Typically this initial strain value will be computed based on an original fractional density of 0.64 (random dense packing of spherical particles) and the fractional density at the beginning of creep consolidation. The modified Spiers model has seven material constants – a, p, Q_s, r_1, r_3, r_4, and n_s, excluding those that appear in the effective stress measure.

2.4 Summary of the Crushed-Salt Consolidation Model

The equation describing the combined crushed-salt constitutive model, which includes dislocation creep and pressure solutioning, is summarized in this section. The final equation for the total creep consolidation strain rate constitutive model for crushed salt is obtained by substituting Equations 2-23 and 2-35 into Equation 2-15:

$$\dot{\epsilon}_{ij}^c = \frac{1}{\sigma_{eq}} \left\{ \frac{r_1 w^a}{d^p} \frac{e^{-\frac{Q_s}{RT}}}{T} \left(\frac{\left(1 + \epsilon_v\right)^{r_3}}{\left|\epsilon_v\right|^{r_4}} \right) \Gamma \sigma_{eq}^f + F \dot{\epsilon}_s \right\} \times$$

$$\left\{ \frac{\kappa_0 \Omega^{\kappa_1} \sigma_m}{3} \delta_{ij} + \kappa_2 \left(\frac{2-D}{D} \right)^{\frac{2n}{n+1}} \left(2 \cos\psi \sqrt{J_2}\right) \left(\left[\frac{\cos 2\psi}{\cos 3\psi}\right] \frac{s_{ij}}{\sqrt{J_2}} + \left[\frac{\sqrt{3}\sin\psi}{J_2 \cos 3\psi}\right] t_{ij} \right) \right\} \tag{2-37}$$

As the material approaches full consolidation, the fractional density approaches 1 and the M-D model creep component becomes the same as that for intact salt. Simultaneously the pressure solutioning portion of the model diminishes as the material approaches full consolidation. This decrease is implemented through the geometric Γ function, which becomes zero at full consolidation. Thus, at complete consolidation (i.e., $D = 1$), Equation 2-37 may be written as:

$$\dot{\epsilon}_{ij}^{c} = \sqrt{\kappa_2}\, F\, \dot{\epsilon}_s \left(\left[\frac{\cos 2\psi}{\cos 3\psi} \right] \frac{s_{ij}}{\sqrt{J_2}} + \left[\frac{\sqrt{3}\sin\psi}{J_2 \cos 3\psi} \right] t_{ij} \right) \tag{2-38}$$

which is identical to the M-D model for intact salt, provided $\kappa_2 = 1$. This condition is easily met by modifying κ_0 appropriately. Substitution of α and β given in Equation 2-17 into Equation 2-20 gives:

$$\mathbf{R} = \frac{\dfrac{\kappa_0 \Omega^{\kappa_1} \sigma_m}{3} + \dfrac{\kappa_2}{2} \left[\dfrac{2 - D}{D} \right]^{\frac{2n}{n+1}} \sqrt{3 J_2}}{\dfrac{\kappa_0 \Omega^{\kappa_1} \sigma_m}{3} - \kappa_2 \left[\dfrac{2 - D}{D} \right]^{\frac{2n}{n+1}} \sqrt{3 J_2}} \tag{2-39}$$

Dividing the numerator and denominator in Equation 2-39 by κ_2 gives:

$$\mathbf{R} = \frac{\dfrac{\kappa_0 \Omega^{\kappa_1} \sigma_m}{\kappa_2 3} + \dfrac{1}{2} \left[\dfrac{2 - D}{D} \right]^{\frac{2n}{n+1}} \sqrt{3 J_2}}{\dfrac{\kappa_0 \Omega^{\kappa_1} \sigma_m}{\kappa_2 3} - \left[\dfrac{2 - D}{D} \right]^{\frac{2n}{n+1}} \sqrt{3 J_2}} \tag{2-40}$$

Thus, if κ_0 is scaled by κ_2 and κ_2 is set equal to one, the appropriate strain rate ratio is maintained and the M-D model is produced exactly when $D = 1$. Therefore the described model provides a smooth transition from crushed salt to intact salt behavior.

3.0 EXPERIMENTAL DATABASE

A database of crushed-salt consolidation laboratory test results was assembled, analyzed, and reported in previous work (Callahan et al., 1995; 1996). This previous work started the process of formulating the functional form of a constitutive model for crushed salt and assembled existing test data into a database to obtain quantitative estimates for the material parameters appearing in the model. The assembled database consists of a collection of tests conducted for a variety of reasons. Thus the database contains biases and shortcomings when viewed strictly from the standpoint of developing constitutive models. The crushed-salt constitutive model has deviatoric and mean stress components that drive the strain response, and the database has shear and hydrostatic consolidation test results used for evaluating the parameters within those respective stress components. When circumstances allow, additional tests are conducted to fill gaps in the database. Two additional shear consolidation tests (RE/SPEC Inc. [1996] and Callahan et al. [1996]) were conducted and added to the database during our most recent work. These two tests represent the first tests with high initial fractional densities (near 0.8) that emulate intact salt behavior accompanied by volumetric consolidation. Associated with the current study, additional laboratory work was conducted to add test data to the shear consolidation portion of the extant database because that portion of the database was relatively sparse, particularly in the higher initial fractional density range expected at the WIPP. The remainder of this chapter is divided into two sections: the first summarizes the status of the database, and the second presents details on the four shear consolidation tests that were performed as part of the current effort.

3.1 Summary of Existing Test Data

The creation of the database being used for parameter estimation began with an extensive library search and compilation of potentially useful test results (Pfeifle, 1995). That compilation was reviewed to document those tests deemed inappropriate for parameter estimation, and the surviving tests formed the database for parameter estimation work (Callahan et al., 1995). Two subsequent shear consolidation tests were added to the database for recent parameter estimation work (Callahan et al., 1996). That database was constructed from two types of tests: hydrostatic consolidation and shear consolidation. The two parts of the database are shown separately here in Tables 3-1 and 3-2, which summarize the tests for the hydrostatic and shear consolidation groupings, respectively.

(a) Grain size was assumed to be 0.5 because dynamic compacted reduces grain sizes.

Table 3-1 lists the 40 tests contained in the hydrostatic consolidation portion of the database. All the testing was performed in a drained condition; i.e., the pore pressure was zero. The database discussed by Callahan et al. (1995) contained 45 tests. Five of the hydrostatic consolidation tests were eliminated from the database as recommended by Callahan et al. (1995). These tests were performed under saturated conditions and were not very well drained, which resulted in the generation of pore pressures with reduced deformation. The maximum and minimum principal stresses are listed under the columns titled σ_1 and σ_3. The principal stresses are equal for the hydrostatic case, but the formatting of the table has been maintained for both types of tests. The initial dry density of the specimens, the density at the beginning of the consolidation stage, and the final density at the end of the test are given under the respective column headings titled ρ_o, ρ_i, and ρ_f.

Table 3-2 lists the shear consolidation tests in the database and is formatted like Table 3-1. The table contains the twelve tests that were used in previous work and another four tests that are part of the current work, which is reported in the next section. As with the hydrostatic consolidation tests, all the shear consolidation tests were performed in a drained condition.

The tests listed in Tables 3-1 and 3-2 comprise the entire database used for parameter estimation in Chapter 4. The original data files often contained thousands of data points and were of impractical size for regression analysis. Each data file was reduced in size to create representative data sets containing only 100 data points, with the first and last data points always being retained and the remaining data points uniformly sampled. This sampling technique is the same as was used in previous work.

3.2 Description of Recent Shear Consolidation Tests

Four shear consolidation creep tests were performed on dynamically compacted crushed-salt specimens that were fabricated with a laboratory scale device following a procedure similar to that used for dynamic compaction of large-scale samples (Hansen and Ahrens, 1996). This device served as a simulant of the compaction technique envisioned for the shaft sealing design. The laboratory scale device used two Proctor split compaction molds to receive the disaggregated salt. After compaction, the molds were removed and the ends of the cylindrical samples were machined to produce testable specimens with nominal dimensions of 100 millimeters in diameter and 200 millimeters in length. The starting material was wetted with a brine, so the specimen moisture content was nominally 1.6 percent by weight. The dry density of the specimens was about 1,985 kg/m^3, which is a fractional density of approximately 0.9 (assuming intact salt density of 2,160 kg/m^3). The energy input to create this density was approximately 2.6 times the modified Proctor energy. The specimens fabricated with the laboratory scale device were identified with the unique labels, RS/DCCS/*n*, where *n* took on values of 1, 2, 3, etc. to designate individual specimens.

The four shear consolidation tests were effectively standard triaxial compression creep tests ($\psi = \pi/6$), and typical test procedures have been described previously (Callahan et al., 1995; Brodsky, 1994). The specimens were initially loaded hydrostatically to the level of specified confining pressure (radial stress) and allowed to stabilize. The specified confining pressure levels for the four tests were –1, –2, –3, and –4 MPa, respectively. Data were collected during the hydrostatic loading phase. Following stabilization, the axial compressive stress for each test was increased by 4 MPa while holding the confining pressure constant so that each of the four specimens was subjected to a stress difference of $\Delta\sigma = 4$ MPa; only the confining pressure was different among tests. Data were also acquired when the axial stress difference was applied. After the axial stress difference was imposed, it was held constant at $\Delta\sigma = 4$ MPa while data were acquired during the shear consolidation creep phase. The test matrix for the shear consolidation creep tests is shown in Table 3-3, where the first column contains the specimen identification and the following three columns give the axial stress, lateral stress, and

temperature, respectively. All four tests were performed in a drained condition; i.e., the pore pressure was zero.

Table 3-3. Shear Consolidated Creep Test Matrix

Specimen Identification	Test Conditions		
	Axial Stress (MPa)	Lateral Stress (MPa)	Temperature (°C)
RS/DCCS/1	-5	-1	25
RS/DCCS/3	-6	-2	25
RS/DCCS/4	-7	-3	25
RS/DCCS/5	-8	-4	25

Analyses based on the constitutive model predicted that a stress state existed wherein the lateral strain rate would initially be negative (compaction) and then reverse direction and become positive as the specimen density increased. As seen in Table 3-3, the scheme for finding this stress state was to change the mean stress by testing at different confining pressures while holding the axial stress difference constant. The creep strain results from the four tests are compared in Figure 3-1, which plots axial and lateral creep strains as a function of time. A significant observation apparent in Figure 3-1 is the trend appearing in the lateral strain response; that is, the magnitude of the lateral strain rate decreases as the confining pressure (mean stress) increases. A very significant phenomenon was observed in the test performed at a confining pressure of –4 MPa. The lateral strain rate in that test was initially negative (specimen diameter decreasing); after some densification of the specimen, the lateral strain rate decreased and ultimately changed sign and became positive (specimen diameter increasing). This observation is important to the work presented in Chapter 4, where the parameters of the crushed-salt constitutive model are determined.

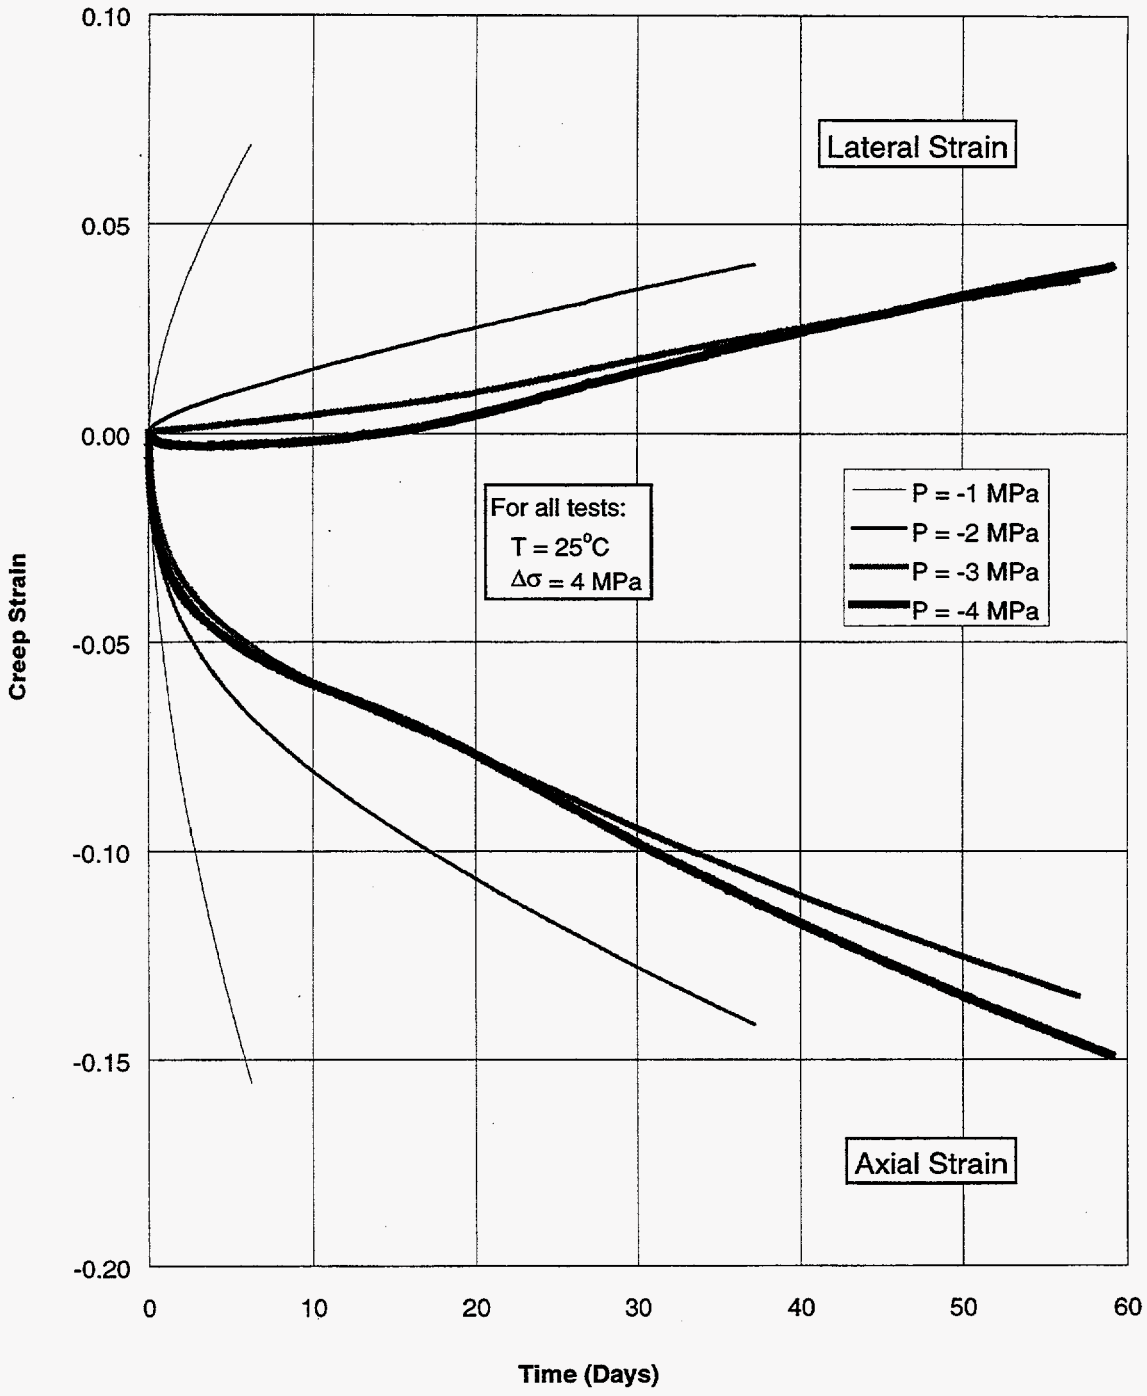

Figure 3-1. Axial and lateral strain as a function of time for four shear consolidation creep tests on dynamically compacted crushed salt.

4.0 MODEL FITTING

4.1 Introduction

The crushed-salt (C-S) constitutive model given in Equation 2-37 contains 33 material parameters. Seventeen of these parameters are contained in the dislocation creep (M-D) portion of the model. The M-D model parameters were fixed at the values provided by Munson et al. (1989) for clean salt. The remaining 16 material parameters consist of 5 flow potential material parameters and 11 creep consolidation parameters. These parameters were determined by fitting the equations that define the C-S constitutive model to the laboratory data such that the weighted squared difference between the measured and calculated response was minimized. First, the flow potential parameters (κ_0, κ_1, κ_2, n, and D_t) were determined by fitting Equation 2-20 (which defines the lateral-to-axial strain rate ratio) to the data measured in the 16 shear consolidation tests. Second, these flow rate parameters were fixed and the 11 creep consolidation parameters (η_0, η_1, η_2, n_f, a, p, n_s, r_1, r_3, r_4, and Q_s/R) were determined by fitting the rate equations that define the axial and lateral strains to the data measured in the 16 shear consolidation and 40 hydrostatic consolidation tests. These nonlinear regressions were performed using the personal-computer platform BioMedical Data Processing (BMDP, Version 7.01) statistical software package (Frane et al., 1985).

4.2 Modeling Procedure

The *object function* is the mathematical function that is to be minimized in the least-squares sense. For example, when performing a least-squares fit of some data to a straight line, the object function is the squared difference between the measured response (the data) and the predicted response from the equation for the straight line. The equation for the straight line when performing linear regression is called the *response model.*

The object function is evaluated at discrete points; these are the points where data have been taken or are available. Some of the measurements may be more important than others and should hold more importance or "weight" than other data points. Mathematically, the relative importance of the level of fit to each data point is accommodated through a *weighting function.*

Application of least squares results in an estimation of the parameters of the response model. In the example cited above, application of least squares will result in the estimation of the two parameters necessary to specify a straight line under the implicit assumption that the measurements will be distributed in the response model for fixed values of the (hopefully)

independent parameters. For complex nonlinear models, the independence of the parameters is not always obvious before fitting. The parameters from the least squares fit to a nonlinear model may not be appropriate if the parameters are highly correlated.

The response model will almost never reproduce all the measurements exactly. The difference between the measured data points and the predicted model response is termed the *residual*. When a weighting function is used in the model fitting, the weighted residual is also of interest. The weighted residual is the usual residual multiplied by the weighting function value for the specific observation or data point.

The object function reflects the relative importance attributed to individual data points and was developed under the following assumptions:

1. Within a given test, there are an equal number of measurement points (100). Each data point was assumed to have equal weight.
2. Within each test, the data are not uniformly distributed with respect to time; the data are denser early in time when the strain rates are highest. Thus the weight function that was used in the model fitting reflects the time step size relative to each data point in each test, such that higher weights are assigned to data points at the end of the test than are assigned to early-time data points.
3. Tests of longer duration were assumed to be more important than tests of shorter duration.
4. Residuals were normalized. They are represented as percent deviations from the measured data. Thus a 10 percent deviation from a very small strain results in the same error in the object function as a 10 percent deviation from a very large strain.

4.2.1 Response Functions

In the shear consolidation tests, there are two independent measurements (superscript m is used to indicate measurements): the volumetric strain $\left(\epsilon_v^m\right)$ and the axial strain $\left(\epsilon_a^m\right)$. The lateral strain $\left(\epsilon_l^m\right)$ was calculated as:

$$\epsilon_l^m = \frac{\epsilon_v^m - \epsilon_a^m}{2} \tag{4-1}$$

The axial strain rate $\left(\dot{\epsilon}_a^m\right)$ was calculated from the measurement of axial strain and elapsed time as follows. At every data point in the original test data file (some contained thousands of

data points), the axial strain rate was calculated as the linear least-square fit to a small interval of data (window) centered on the point in time. The window was then shifted by one data point to the next point in time and the linear fit was repeated. This process was repeated until a point was reached where the width of the window reached the end of the data file for each test. A 50-point window was used in this process. The lateral strain rate $\left(\dot{\epsilon}_l^m\right)$ was calculated in a similar fashion. The measured lateral-to-axial strain rate ratio ($\mathbf{R}^m$) is defined as:

$$\mathbf{R}^m = \frac{\dot{\epsilon}_l^m}{\dot{\epsilon}_a^m} \tag{4-2}$$

Following the development in Chapter 2, the response function used to determine the flow potential parameters is:

$$\mathbf{R}^p = \frac{\alpha + \frac{\beta}{2}}{\alpha - \beta} \tag{4-3}$$

where:

$\mathbf{R}^p$ = predicted lateral-to-axial strain rate ratio

$$\alpha = \frac{\kappa_0 \, \Omega^{\kappa_1} \, \sigma_m}{3}$$

$$\beta = \kappa_2 \left(\frac{2 - D}{D} \right)^{\frac{2n}{n+1}} \left(\sigma_1 - \sigma_3\right)$$

$$\Omega = \left\{ \frac{\left(1 - D_v\right)n}{\left[1 - \left(1 - D_v\right)^{1/n}\right]^n} \right\}^{\frac{2}{n+1}}$$

$$D_v = \begin{cases} D_t & D \le D_t \\ D & D > D_t \end{cases}$$

D = current fractional density

σ_m = mean stress = $(\sigma_3 + 2\sigma_1)/3$

σ_3 = minimum principal stress

σ_1 = maximum principal stress

κ_0, κ_1, κ_2, n, and D_t = flow potential parameters.

Examination of Equation 4-3 reveals that two of the flow potential parameters (κ_0 and κ_2) are not independent of one another (cf., Equation 2-40). Therefore the parameter κ_2 was fixed at a value of 1.0 and the remaining four flow rate parameters were determined in the fit.

The response function (ρ) used to determine the creep consolidation parameters is:

$$\rho = 1 - \left\{\left[\left(1 - R_1\right)^2 + \left(1 - R_2\right)^2\right] wt\right\}^{1/2} \tag{4-4}$$

where:

$R_1 = \epsilon_a^p / \epsilon_a^m$

$R_2 = \epsilon_l^p / \epsilon_l^m$

$wt = \Delta t / \bar{t}$ = weighting function

Δt = time step size

$\bar{t}$ = normalizing time = 10^6(s)

ϵ_l^p = predicted lateral strain = $\int_0^t \dot{\epsilon}_l^p \, dt$

ϵ_a^p = predicted axial strain = $\int_0^t \dot{\epsilon}_a^p \, dt$

$\dot{\epsilon}_l^p$ = predicted lateral strain rate = $\left(\alpha + \beta/2\right) \dfrac{\dot{\epsilon}_{eq}}{\sigma_{eq}}$

$\dot{\epsilon}_a^p$ = predicted axial strain rate = $\left(\alpha - \beta\right) \dfrac{\dot{\epsilon}_{eq}}{\sigma_{eq}}$

$\dot{\epsilon}_{eq}$ = equivalent inelastic strain rate = $\dot{\epsilon}_{eq}^d + \dot{\epsilon}_{eq}^w$

σ_{eq} = equivalent stress measure = $\left[\kappa_0 \, \Omega^{\kappa_1} \, \sigma_m^2 + \kappa_2 \left(\dfrac{2 - D}{D}\right)^{\frac{2n}{n+1}} \left(\sigma_1 - \sigma_3\right)^2\right]^{1/2}$

$\dot{\epsilon}_{eq}^d$ = Munson-Dawson dislocation creep strain-rate model given in Equations 2-23 to 2-32

$\dot{\epsilon}_{eq}^w$ = Spiers pressure-solutioning inelastic strain-rate model given in Equations 2-34 and 2-35

η_0, η_1, η_2, n_f, a, p, n_s,
r_1, r_3, r_4, and Q_s/R = creep consolidation parameters.

The Munson-Dawson dislocation creep model has 17 parameters, which are given in Table 4-1 for clean WIPP salt.

Table 4-1. Munson-Dawson Model Parameter Values for Clean Salt (after Munson et al., 1989)

Parameter	Units	Clean Salt
A_1	yr^{-1} s^{-1}	2.645E+30 8.386E+22
A_2	yr^{-1} s^{-1}	3.050E+20 9.672E+12
Q_1/R Q_1	K cal/mol	12,581 25,000
Q_2/R Q_2	K cal/mol	5,033 10,000
n_1	—	5.5
n_2	—	5.0
B_1	yr^{-1} s^{-1}	1.919E+14 6.0856E+06
B_2	yr^{-1} s^{-1}	9.568E+05 3.034E-02
q	—	5,335

α	—	-17.37
β	—	-7.738
δ	—	0.58

4.2.2 Object Function

The object function is the sum-of-squared errors (SS_E). In determining the flow rate parameters, the sum-of-squared error is defined as:

$$SS_E = \sum_{i=1}^{N} \left(R_i^P - R_i^m\right)^2 \tag{4-5}$$

where:

R_i^P = predicted lateral to axial strain rate for the ith data point (Equation 4-3)

R_i^m = measured lateral to axial strain rate for the ith data point (Equation 4-2)

N = number of data points in test database.

In determining the creep consolidation parameters, the sum-of-squared error is defined as:

$$SS_E = \sum_{i=1}^{N} \left(1 - \rho_i\right)^2 \tag{4-6}$$

where:

ρ_i = response function defined in Equation 4-4 for the ith data point.

4.3 Statistical Measures

One key aspect of the model-fitting effort is deciding if the model fit to one database is better than the fit to the other database. In this section, the statistical measures for evaluating and comparing fits to the candidate constitutive model are discussed.

4.3.1 Weighted Residual

In all types of regression, the residual squared times a weighting function is the function that is minimized, where the residual is defined as the difference between the observed and predicted functional values. The sum-of-squared error term defined in Equation 4-6 was used in evaluating the model fits to the two databases.

The specific weighting function associated with the sum-of-squared error is equal to the reciprocal of the measured axial strain squared $\left(\epsilon_a^m\right)^2$, the reciprocal of the measured lateral strain

squared $\left(\epsilon_l^m\right)^2$, the time increment (Δt), and the reciprocal of a normalizing time (10^6 *s*). Thus, if the response model (Equation 4-4) predicts zero axial strain and zero lateral strain over the duration of all tests in the database, the term SS_E in Equation 4-6 will have a value of twice the number of million seconds in the database. This is termed here the maximum value of the sum-of-squared error $\left(SS_E^{max}\right)$. The 40 hydrostatic consolidation tests constitute a total of 76.0(10^6) *s*. The 16 shear consolidation tests total 69.35(10^6) *s*. Therefore SS_E^{max} = 138.7 in the fit to the shear tests, and SS_E^{max} = 290.7 in the fit to the combined test database.

In a similar fashion, if the response model is a perfect predictor for all the tests in the database, the sum-of-squared error will be exactly zero. This is the minimum value of the sum-of-squared error.

For each model fit, the sum-of-squared error was normalized as follows:

$$0 \leq \overline{SS}_E \leq 1 \tag{4-7}$$

where:

$$\overline{SS}_E = SS_E / SS_E^{max}$$

The normalized sum-of-squared error was used in comparing the two model fits.

4.3.2 Parameter Multicollinearity

When fitting a mathematical relation to a set of laboratory-measured data, it is desirable to have enough information in the measured database to ensure that each of the parameters can be uniquely determined. Two possibilities can occur that will not allow for a unique determination of each parameter in a mathematical relation. First, the mathematical relation may inherently include parameters that are dependent on one another. For example, in the relation:

$$F = A + B \tag{4-8}$$

the parameters *A* and *B* cannot be determined uniquely.

Second, there may not be sufficient data in the database to uniquely determine the magnitude of certain model parameters. For example, there are minimal variations in grain size (*d*), moisture content (*w*), and temperature (*T*) in the shear consolidation tests ($\Delta\sigma \neq 0$). Thus, in fitting the candidate models to these tests, the parameters *p*, *a*, and Q_s/R in the term

$$\xi(d,w,T) = \frac{w^{a}}{d^{p}T} \exp\left(-Q_s/RT\right) \tag{4-9}$$

cannot be uniquely determined.

When either of the two aforementioned conditions exist, a condition of multicollinearity is said to exist (Montgomery and Peck, 1982). An examination of the parameter covariance matrix will determine the degree to which the material parameters are correlated to each other. The higher the parameter covariance, the higher the parameter collinearity. When a multicollinearity situation exists, one must (1) expand the database of measurements or (2) modify the functional form of the model.

The elements of the correlation matrix (C_{ij}) can be expressed as:

$$C_{ij} = \frac{q_{ij}}{\sqrt{q_{ii}\, q_{jj}}} \tag{4-10}$$

where:

$q_{ij} = \left[z_{ip}\, z_{pj}\right]^{-1}$

$z_{ij} = \dfrac{\partial\, \epsilon^{m}\left(x_j, \bar{p}\right)}{\partial p_i}$

$\bar{p}$ = set of parameters taken at their mean values

p_i = i^{th} parameter

x_j = j^{th} model variable

ϵ^{m} = measured response.

If the parameters are uncorrelated, then $C_{ij} = 0$. Conversely, the correlation coefficient is one if the parameters are totally correlated. The parameters are highly correlated if $C_{ij} \geq 0.90$, and a state of parameter multicollinearity may exist.

A scalar quantity, termed the parameter correlation measure (pcm), was used in this study as a global measure of the parameter correlations associated with each model's fit to each database. This measure is defined as:

$$\text{pcm} = \frac{\sum_{i=1}^{p-1} \sum_{j=p}^{i+1} C_{ij}^2}{\sum_{i=1}^{p-1} i} = \frac{2 \sum_{i=1}^{p-1} \sum_{j=p}^{i+1} C_{ij}^2}{p^2 - p} \tag{4-11}$$

where p is the number of parameters in the model and $0 \leq \text{pcm} \leq 1$. The numerator in Equation 4-11 is the sum of the squares of the lower triangular components of the parameter correlation matrix (Equation 4-10), and the denominator simply normalizes the result by the number of components in the sum. Obviously, lower parameter correlations will reduce the magnitude of the parameter correlation measure. Finally, an average parameter correlation $(\bar{c})$ can be quantified as:

$$\bar{c} = \sqrt{\text{pcm}} \tag{4-12}$$

4.3.3 Parameter Variation Among Fits

The C-S constitutive model was fit to two databases: (1) the shear consolidation tests only and (2) the combination of shear and hydrostatic consolidation tests. If a specific model is truly a constitutive law in representing the consolidation of crushed salt, the material parameters in each of the different fits should be the same or nearly the same. To evaluate the parameter variation in each of the models, comparisons of the parameter values determined in the fits to the shear consolidation tests were made to the parameter values determined in the fit to the combined database. The ratio of the number of parameters that changed by more than one order of magnitude to the total number of model parameters was calculated for each of the fits to the hydrostatic and shear consolidation tests.

4.3.4 Predictive Capability

The aptness of each of the candidate models (predictive capability) can be demonstrated using the parameter values determined by fitting to the individual test databases. The material parameters determined in the fit to the shear consolidation tests were used to predict each of the hydrostatic consolidation tests. A quantitative measure of the predictive capability is simply the

sum-of-squared error (Equations 4-5 and 4-6). This measure was calculated using the BMDP Program AR (Section 4.4) by fixing the parameter values at those determined in the fit to the shear consolidation tests and fitting (predicting) the hydrostatic consolidation tests.

4.4 BMDP Statistical Software

This section describes in detail the BMDP nonlinear regression Programs 3R and AR used in the model fitting. BMDP is a statistical software package developed at the University of California at Berkeley, supported by grants from the Biotechnology Resources Branch of the National Institutes of Health and the National Science Foundation.

BMDP Program AR is a nonlinear regression program that estimates the parameters of a nonlinear function by least squares using a pseudo Gauss-Newton algorithm. The response model can be specified as a system of coupled rate equations. The response model derivatives are evaluated numerically based on the initial parameter estimates and are not updated during the regression. In addition to calculating the weighted sum-of-squared error (SS_E), the program calculates the coefficient of multiple determination (R_p^2), the residual mean-squared error (MS_E), and the coefficients of the parameter correlation matrix (C_{ij}). The various program features and supporting documentation of AR are provided in various BMDP technical reports, including Frane et al. (1985). Program AR was used in determining the creep consolidation parameters.

BMDP Program 3R is identical to AR with the following exceptions: (1) the model function cannot be expressed as a system of coupled rate equations and (2) the response model derivatives are updated continuously during the regression. Program 3R was used in determining the flow potential parameters.

The input files required to execute an AR or 3R analysis are described in detail by Dixon et al. (1985) and in the BMDP Users' Digest (Hill, 1984). Basically the input files can be thought of as a series of paragraphs that are further subdivided into sentences using keywords. Each paragraph is activated by a slash (/) followed immediately by a keyword. Each of these sentences are activated by keywords and ended with periods. All comment cards are noted using the pound symbol (#). The BMDP input files for the model fits are given in Appendix A.

The BMDP input files are composed of 12 paragraphs. The first paragraph (/INPUT) contains the title card, the database file name, the format to be used in reading the data, and the number of variables in the database. The second paragraph (/VARIABLES) names each of the 18 variables contained in the database file. The third paragraph (/TRANS) identifies the defined

variables (or functions of variables) that are specific to the response model. Specifically, MS and DS are the mean stress and stress difference, respectively. Similarly, D0 and DI are the emplaced and initial fractional density, respectively. The variable USE identifies which test database is to be used in the fit, and the variable WT is the weight function. The fourth paragraph (/REGRESS) identifies the dependent variable (DEPEND), the number of parameters in the model, the weight function variable (WEIGHT), the integration variable (ITIME) in the rate equations, the number of differential equations (NEQN), the number of iterations (ITER), the number of interval halvings for each iteration (HALVINGS), and the maximum number of integration steps (MAXC). The fifth paragraph (/PARAMETER) identifies the parameter names and the initial estimates, as well as the maximum and minimum values for each of the parameters. The sixth paragraph (/DIFIN) identifies the initial values for each of the dependent variables in the rate equations (Z(i),i=1,NEQN). The seventh paragraph (/DIFEQ) specifies the functional form of the rate equations (DZ(i), i=1,NEQN). The eighth paragraph (/FUN) identifies the dependent variable (response) function (F). The ninth through eleventh paragraphs (/SAVE, /PRINT, and /PLOT) specify output options for the program. The last paragraph (/END) identifies the end of the input file.

4.5 Results

In this section the results of the model fits are presented and discussed in terms of the model parameters and the statistical measures defined in Section 4.3.

The C-S constitutive model contains a total of 16 parameters. Five of these parameters are termed the flow potential parameters (κ_0, κ_1, κ_2, n, and D_t). These parameters were determined by fitting the C-S constitutive model to the lateral-to-axial strain rate ratios measured in the 16 shear consolidation tests. The remaining 11 parameters in the C-S constitutive model are termed the creep consolidation parameters (η_0, η_1, η_2, n_f, a_1, p, n_s, r_1, r_3, r_4, and Q_s/R). Two sets of creep consolidation parameters were determined: one set each resulting from fits to a database composed of 16 shear consolidation tests and to a combined database composed of the 16 shear and 40 hydrostatic consolidation tests. The parameters were determined by fitting the C-S constitutive model to the axial and lateral strains measured in each of the tests. The parameters η_0, η_1, η_2, and n_f define the stress measure σ_{eq}^{f}. Moisture dependence, grain-size dependence, and temperature dependence are defined by the parameters a, p, and Q_s/R, respectively. The remaining parameters (r_1, r_3, and r_4) are for the Spiers pressure-solutioning model (Equation 2-35). In both fits, the parameter η_2 was fixed at unity, ensuring that the C-S constitutive model smoothly transitions into the M-D dislocation creep model at a fractional density of 1.0, according to Equation 2-8.

4.5.1 Flow Potential Parameters

The flow potential parameters are given in Table 4-2. Plots of the predicted and measured lateral-to-axial strain rate ratios as a function of density for each of the 16 shear consolidation tests are given in Appendix B.

Table 4-2. Flow Potential Parameters

Parameter	Magnitude	Units
K_0	0.095	—
K_1	1.412	—
K_2	1.000	—
n	7.578	—
D_t	0.891	—

4.5.2 Creep Consolidation Parameters

The creep consolidation parameters for each of the two model fits are given in Table 4-3. Plots of the predicted and measured lateral and axial strains for each of the 16 shear consolidation tests and 40 hydrostatic consolidation tests are given in Appendix C.

4.6 Statistical Measures

4.6.1 Sum-of-Squared Error

The sum-of-squared error (SS_E) was calculated using Equation 4-5 for each of the model fits to the shear test database and the combined test database. Using these results and Equation 4-7, the normalized sum-of-squared error $\left(\overline{SS}_E\right)$ was calculated for each of the model fits. The results are given in Table 4-4.

Table 4-3. Creep Consolidation Parameters

Parameter	Units	Shear Tests	Combined Tests
η_0	—	0.1319	$2.581(10^{-2})$
η_1	—	3.9387	2.587
η_2	—	1.000	1.00
n_f	—	3.5122	4.792
a	—	0.3179	0.0230
p	—	1.6366	1.099
n_s	—	0.1209	0.0
r_1	m^p•k(MPa•s)	$3.58(10^{-4})$	$5.53(10^{-4})$
r_3	—	6.7325	11.12
r_4	—	0.0	0.6003
Q_s/R	K	1074.5	811.28

Table 4-4. Sum-of-Squared Error, SS_E

Test Database	SS_E	$\overline{SS}_E$
Shear	10.41	0.075
Combined	37.9	0.130

These results indicate that the model fit to the shear test database is qualitatively better than the fit to the combined tests (i.e., 7 percent relative error in comparison to 13 percent relative error).

4.6.2 Parameter Multicollinearity

The parameter correlation coefficient matrices for each of the two model fits are given in Tables 4-5 and 4-6. High parameter correlations (>0.90) are indicative of possible parameter multicollinearity. As noted in Section 4.3.2, high parameter correlations are indicative of either (1) deficiencies in the functional form of the C-S constitutive model or (2) deficiencies (or gaps) in the test database.

Table 4-5. Parameter Correlation Coefficient Matrix—Model Fit to Shear Consolidation Tests

	n_t	η_0	η_1	a	p	n_s	r_1	r_s	r_4	Q_s/R
n_t	1.0									
η_0	0	1.0								
η_1	-1.0	0	1.0							
a	0	0.1161	0	1.0						
p	0	0.2081	0	0.8733	1.0					
n_s	0	-0.0359	0	-0.3507	-0.3923	1.0				
r_1	0	-0.1910	0	-0.9088	-0.9716	0.3375	1.0

In general, most of the parameter correlations are low (<0.90) for both fits. However, four sets of parameters in the fit to the shear test database ($n_f - \eta_1$, $a_1 - r_4$, $p - r_1$, and $r_3 - Q_s/R$) and three sets of parameters in the fit to the combined test database ($n_f - \eta_1$, $r_1 - r_4$, and $r_3 - Q_s/R$) have correlation coefficients greater than 0.90.

The parameter correlation measure (pcm) and the average correlation coefficient $(\bar{c})$ were evaluated using Equations 4-11 and 4-12, respectively. The results are given in Table 4-7 for each of the model fits.

Table 4-7. Parameter Correlation Measure

Test Database	pcm	$\bar{c}$
Shear	0.200	0.447
Combined	0.120	0.346

The results in Table 4-7 indicate that the parameters are slightly less correlated in the fit to the combined test database. However, the average correlation coefficient is less than 0.5 in both fits, which indicates that the possibility of parameter multicollinearity is low.

4.6.3 Parameter Variation Among Fits

A quantitative measure of the parameter variation between the C-S constitutive model fits to the two databases was defined in Section 4.3.5. The measure simply indicates the percentage change in each of the parameter values in the fit to the combined test database as compared to the parameter value determined in the model fit to the shear consolidation tests. The variation in parameter values in the fit to the combined test database is given in Table 4-8. As can be seen in this table, no parameters varied by more than one order of magnitude (i.e., parameter variation >10). Qualitatively the parameters did not change appreciably overall in the two model fits.

4.6.4 Predictive Capability

The predictive capability of the C-S constitutive model is measured qualitatively by how successfully the model fits to the shear consolidation tests predict the hydrostatic consolidation tests. Figures showing the C-S constitutive model fits to the hydrostatic consolidation tests are given in Appendix C, specifically Figures C-1 through C-40. The sum-of-squared error in predicting the hydrostatic consolidation tests was calculated using Equation 4-6. These results are given in Table 4-9.

Visual examination of Figures C-17 to C-28 reveals that the model fit to the shear test database does not predict the hydrostatic tests that are dry ($w = 0$), particularly as the mean stress increases. Therefore the shear database model parameters were used to predict the wet hydrostatic consolidation tests. As seen in Table 4-9, the sum-of-squared error in predicting these tests (22.84) is nearly identical to that determined in the model fit to the combined tests (22.00).

Table 4-8. Parameter Variation

Parameter	Variation (%)
η_0	19
η_1	66
n_f	136
a_1	7
p	67
n_s	0
r_1	149
r_3	165
r_4	0
Q_s/R	75

Table 4-9. Sum-of-Squared Error in Hydrostatic Consolidation Tests

Database Fit	Database Predicted	
	Hydrostatic	Wet Hydrostatic
Shear	$>10^{22}$	22.84
Combined	23.61	22.00

These results suggest that the crushed-salt constitutive model (with parameter values determined from the shear consolidation tests) has excellent predictive quality. As shown in Table 4-9, this form of the model *predicts* the wet hydrostatic tests nearly as well as the model *fits* to the same tests. As further evidenced in the figures in Appendix C, visual comparison of the two fits shows qualitative sameness, even though the parameter values themselves might appear to be quite different (Table 4-3). For some tests (e.g., CS3 and CS9) the shear-determined parameters predict the laboratory data even better than the fit. Furthermore the model contains both a volumetric (hydrostatic) component and a deviatoric (shear) component, both of which are

captured in the shear consolidation tests. This provides a good sense of compatibility between theory (the model) and reality (the data). Thus the model not only characterizes (fits) the shear data well; it can also reproduce (predict) simpler conditions nearly as well. This provides strong evidence that the model has the potential for predicting the consolidation of crushed salt in other, more complex conditions, including the behavior of the shaft seal.

5.0 MODEL COMPARISONS

Over the past 20 years the behavior of particles has received growing interest in an effort to optimize manufacturing processes for forming parts from metallic powders and ceramics. On the surface, the task of predicting the behavior of a well-characterized material changed only by the introduction of voids would seem to be a straightforward process. However, the task is much more formidable because of the idealized, continually changing geometry and potential changes in the micromechanisms themselves over a wide range of porosity. Much of the research conducted to date is derived from cell models (i.e., a single void surrounded by the matrix material) analyzed to develop microscopic models that are homogenized to produce a macroscopic model of a void-filled material. Naturally the single cell models do not behave exactly like aggregates with random void distributions, nor do they account for interaction of the voids. Thus bounding solutions are typically derived that provide estimates for the random aggregate assemblage. Cell model analysis methods have mainly included analytical solutions and finite element analyses. Analytical solutions are usually derived for the simpler void geometries, which are typically spherical or cylindrical with preferred orientations. Then macroscopic solutions are derived that bound the microscopic cell solutions. Finite element analyses have been applied to problems similar to the analytical solution cell geometries, but they also provide flexibility in void shape and orientation. Hypothesized macroscopic constitutive models are matched to the cell behavior resulting from the finite element analyses. In this chapter, the effective stress measure for the crushed-salt flow potential is compared to each of these model types. The analytical model was developed by Gurson (1977) and later modified by Tvergaard (1981), and the finite element unit cell calculation-assisted model was developed by Sofronis and McMeeking (1992). Gurson's and Tvergaard's models are classic models for voided material that are cited by numerous researchers. Thus the crushed-salt model is compared with their models to enhance our understanding of the crushed-salt model predictive ability over a wide range of fractional densities and stress triaxialities. The Sofronis and McMeeking model forms the basis for the crushed-salt model. Comparison with this model shows the effect of modifications aimed at making the model more representative of crushed salt. Comparisons to these models are discussed separately in the remainder of this chapter.

5.1 Gurson and Tvergaard Models Comparison

Gurson (1977) developed approximate yield criteria and flow rules for porous ductile materials. Previous plastic models relied on the deviatoric response of the material matrix predicting incompressibility and could not predict the dilational aspects evident in porous inelastic materials. Gurson used simple cell models to develop upper bound yield loci to provide an approximate picture of the role of the hydrostatic stress in the yield and flow of porous, ductile

materials. Gurson considered long, circular, cylindrical voids and spherical voids as the void geometries. Later, Tvergaard (1981) recommended a modification to Gurson's model based on his numerical calculations to account for void interaction.

Comparison of the crushed-salt flow potential function (described in Chapter 2) to Gurson's and Tvergaard's models may help bring a physical basis to the crushed-salt model. However, at the outset we must recognize a significant difference between these earlier plastic models and the crushed-salt model. The plastic models are concerned with void nucleation and growth causing bulk dilatancy, which commonly accompanies large plastic flow. Thus the plastic models attempt to capture the increase in volume, whereas the crushed-salt model attempts to capture the decrease in volume. However, for the most part, consistency of the dilatancy terms is accomplished by the accompanying change in sign of the mean stress from tension to compression.

The yield or plastic potential function (F) developed by Gurson and modified by Tvergaard can be written as:

$$F = \left(\frac{\sigma_e}{\sigma_0}\right)^2 + 2q_1(1 - D)\cosh\left(\frac{3\alpha q_2 \hat{\sigma}}{2\sigma_0}\right) - \left[1 + q_3(1 - D)^2\right] \tag{5-1}$$

where:

$$\sigma_e = \left(\frac{3}{2}s_{ij}s_{ij}\right)^{1/2} = \sqrt{3J_2}, \text{ von Mises effective stress}$$

$$s_{ij} = \sigma_{ij} - \sigma_m\delta_{ij}, \text{ deviatoric stress}$$

$$\hat{\sigma} = \begin{cases} \sigma_p, \text{ in-plane mean stress (cylindrical voids)} \\ \sigma_m = \dfrac{\sigma_{kk}}{3}, \text{ mean stress (spherical voids)} \end{cases}$$

$$\alpha = \begin{cases} \sqrt{3}, & \text{cylindrical voids} \\ 1, & \text{spherical voids} \end{cases}$$

$$q_1, q_2, q_3 = \begin{cases} q_1 = q_2 = q_3 = 1, & \text{Gurson model} \\ q_1 = 1.5,\ q_2 = 1,\ q_3 = q_1^2, & \text{Tvergaard model} \end{cases}$$

D = fractional density

σ_0 = material equivalent yield stress.

The variable σ_p is the partial trace of the stress tensor in the plane orthogonal to the axis of the void for the cylindrical void model and the mean stress for the spherical void model. Equation 5-1 describes the level or magnitude of stress required to yield a porous, plastic material as described by Gurson and Tvergaard. The direction of flow is described by the normal to the yield surface and defined as the derivative of the yield function with respect to stress for associative flow. For comparative purposes, the effective stress measure used to describe the crushed-salt flow potential is used, which is given in Equation 2-3 and repeated here for convenience.

$$\sigma_{eq} = \left[\kappa_0 \Omega^{\kappa_1} \sigma_m^2 + \kappa_2 \left(\frac{2 - D}{D} \right)^{\frac{2n}{n+1}} (\sigma_1 - \sigma_3)^2 \right]^{\frac{1}{2}} \tag{5-2}$$

To aid in comparing the crushed-salt equivalent stress with Gurson's and Tvergaard's models, Equation 5-2 is rewritten as a similar type of yield function (F_{cs}) as:

$$F_{cs} = \left[\kappa_0 \Omega^{\kappa_1} \sigma_m^2 + \kappa_2 \left(\frac{2 - D}{D} \right)^{\frac{2n}{n+1}} (\sigma_1 - \sigma_3)^2 \right]^{\frac{1}{2}} - \left[1 + (1 - D)^2 \right]^{\frac{1}{2}} \tag{5-3}$$

The added term in Equation 5-3 makes the magnitudes of the effective stress similar to the magnitudes predicted by Gurson's and Tvergaard's yield functions. However, the flow direction is unaffected by the additional term because the derivative of Equation 5-3 with respect to stress remains the same as that for Equation 5-2. In this comparison, the shapes of the resulting curves are most important because Equation 5-2 governs the direction of flow for the crushed-salt model.

To aid in a numerical comparison of the models, consider a triaxial compression test where:

$$\begin{aligned} &\sigma_3 < \sigma_1 = \sigma_2 \\ &\sigma_e = \sqrt{3 J_2} = \sigma_1 - \sigma_3 = \Delta\sigma \end{aligned} \tag{5-4}$$

Substituting Equation 5-4 into Equations 5-1 and 5-3 and solving for $\Delta\sigma$ at yield ($F = F_{cs} = 0$) gives:

$$\Delta\sigma = \left[-2q_1(1 - D)\sigma_0^2 \cosh\left(\frac{3\alpha q_2 \sigma_m}{2\sigma_0} \right) + \left(1 + q_3[1 - D]^2\right)\sigma_0^2 \right]^{1/2} \tag{5-5}$$

for Gurson's and Tvergaard's model and

$$\Delta\sigma_{cs} = \left[\frac{1}{\kappa_2} \left(\frac{2 - D}{D} \right)^{\frac{-2n}{n+1}} \left(-\kappa_0 \Omega^{\kappa_1} \sigma_m^2 + 1 + [1 - D]^2 \right) \right]^{1/2} \tag{5-6}$$

for the crushed-salt model. Substitution of mean stress values produces effective stress (stress difference) values that form data pairs for plotting in stress space.

To compare Equations 5-5 and 5-6, fractional density values of 0.9, 0.8, and 0.7 or porosity values ($\phi = 1 - D$) of 0.1, 0.2, and 0.3 are assumed. The crushed-salt model parameter values given in Chapter 4 (Table 4-2) are used in the comparison. For Gurson's and Tvergaard's models, σ_0 is taken to equal one. Figures 5-1 and 5-2 are compressive stress space plots that compare the crushed-salt model to Gurson's and Tvergaard's models for spherical voids and long, circular, cylindrical voids, respectively. As shown in Figure 5-1, the crushed-salt model shape is most similar to Gurson's and Tvergaard's model shapes at the lowest fractional density. In addition, the crushed-salt model appears to be less sensitive to changes in fractional density. Comparison to the cylindrical void form of Gurson's and Tvergaard's models given in Figure 5-2 is academic because the cylindrical void model includes the partial trace of the stress tensor normal to the axis of the void, whereas the crushed-salt model includes the mean stress. Thus the abscissa is different for the models as labeled in Figure 5-2. However, it is still interesting that the crushed-salt model appears to compare most closely with Gurson's and Tvergaard's cylindrical void model at the higher fractional densities, which is the opposite of what was observed in Figure 5-1 for the spherical void model.

5.2 Sofronis and McMeeking Model Comparison

Sofronis and McMeeking (1992) conducted finite element calculations for a unit spherical cell containing a concentric spherical hole to characterize a power-law creep material containing voids. Calculations were carried out for isostatic and nonisostatic cases. Based on the results of

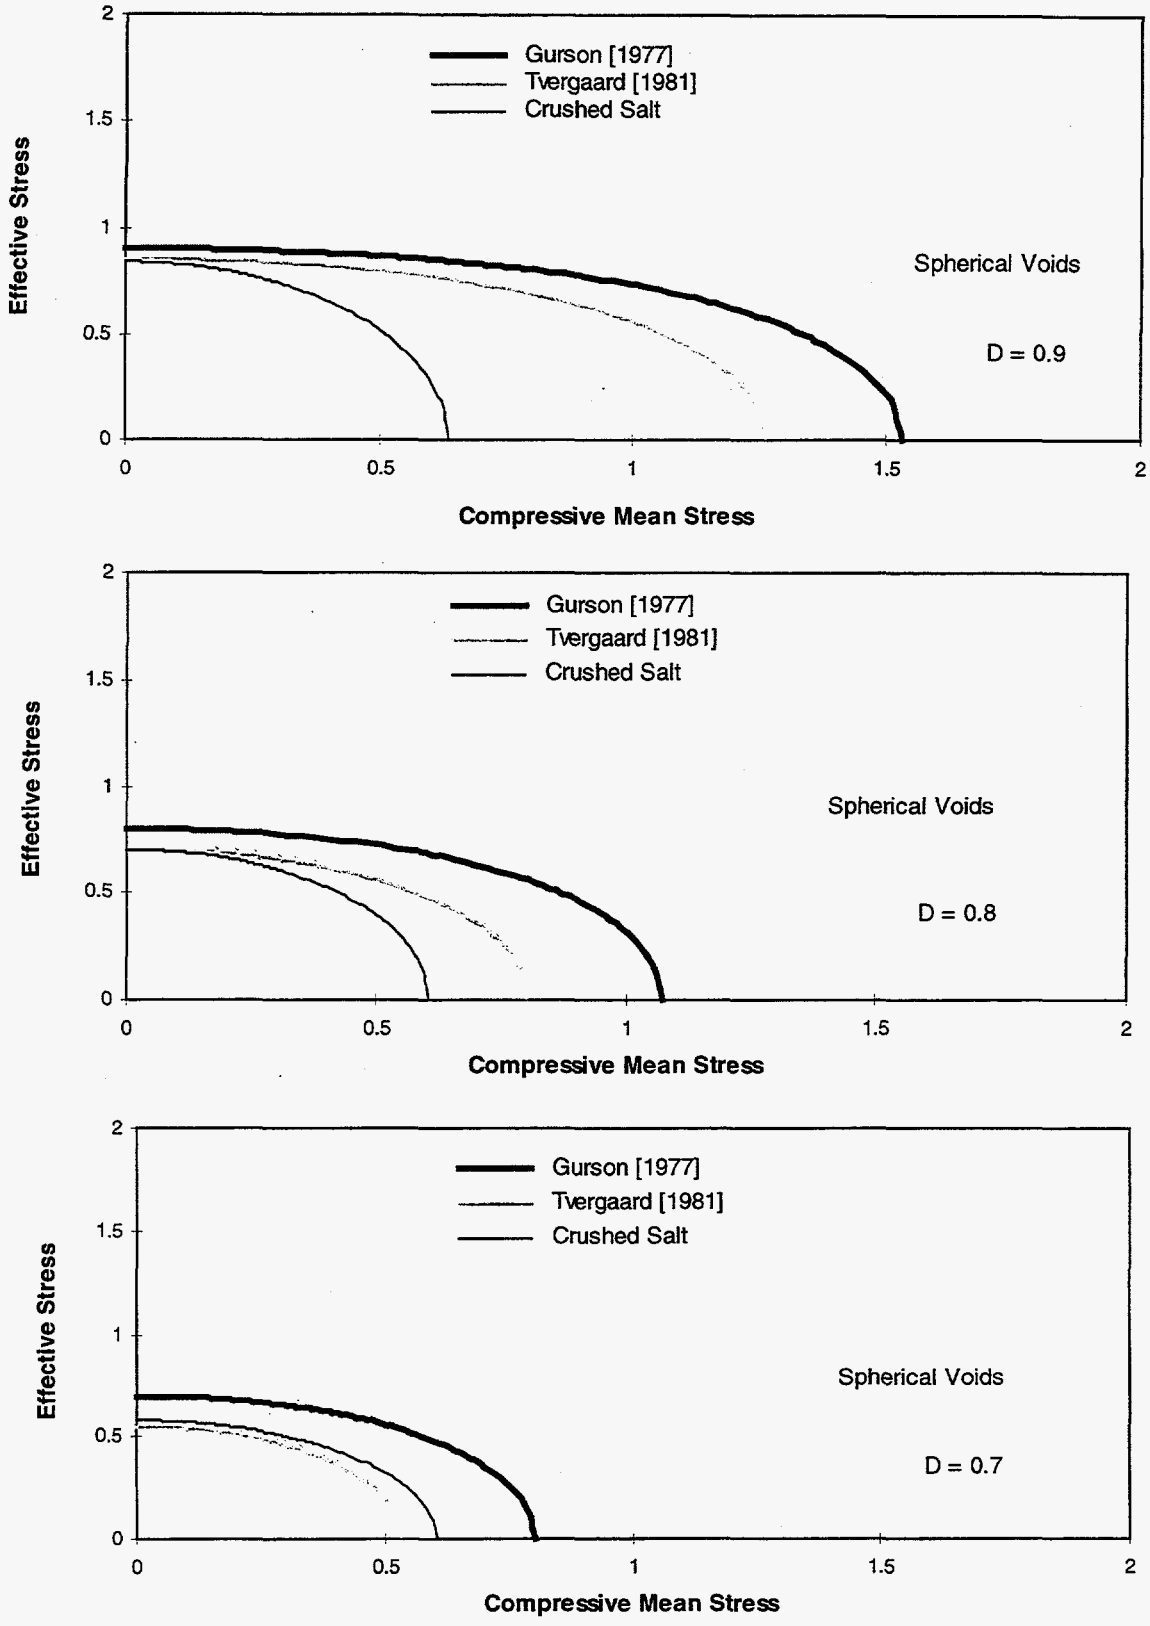

Figure 5-1. Comparison of the crushed-salt model to Gurson's and Tvergaard's models, assuming spherical voids.

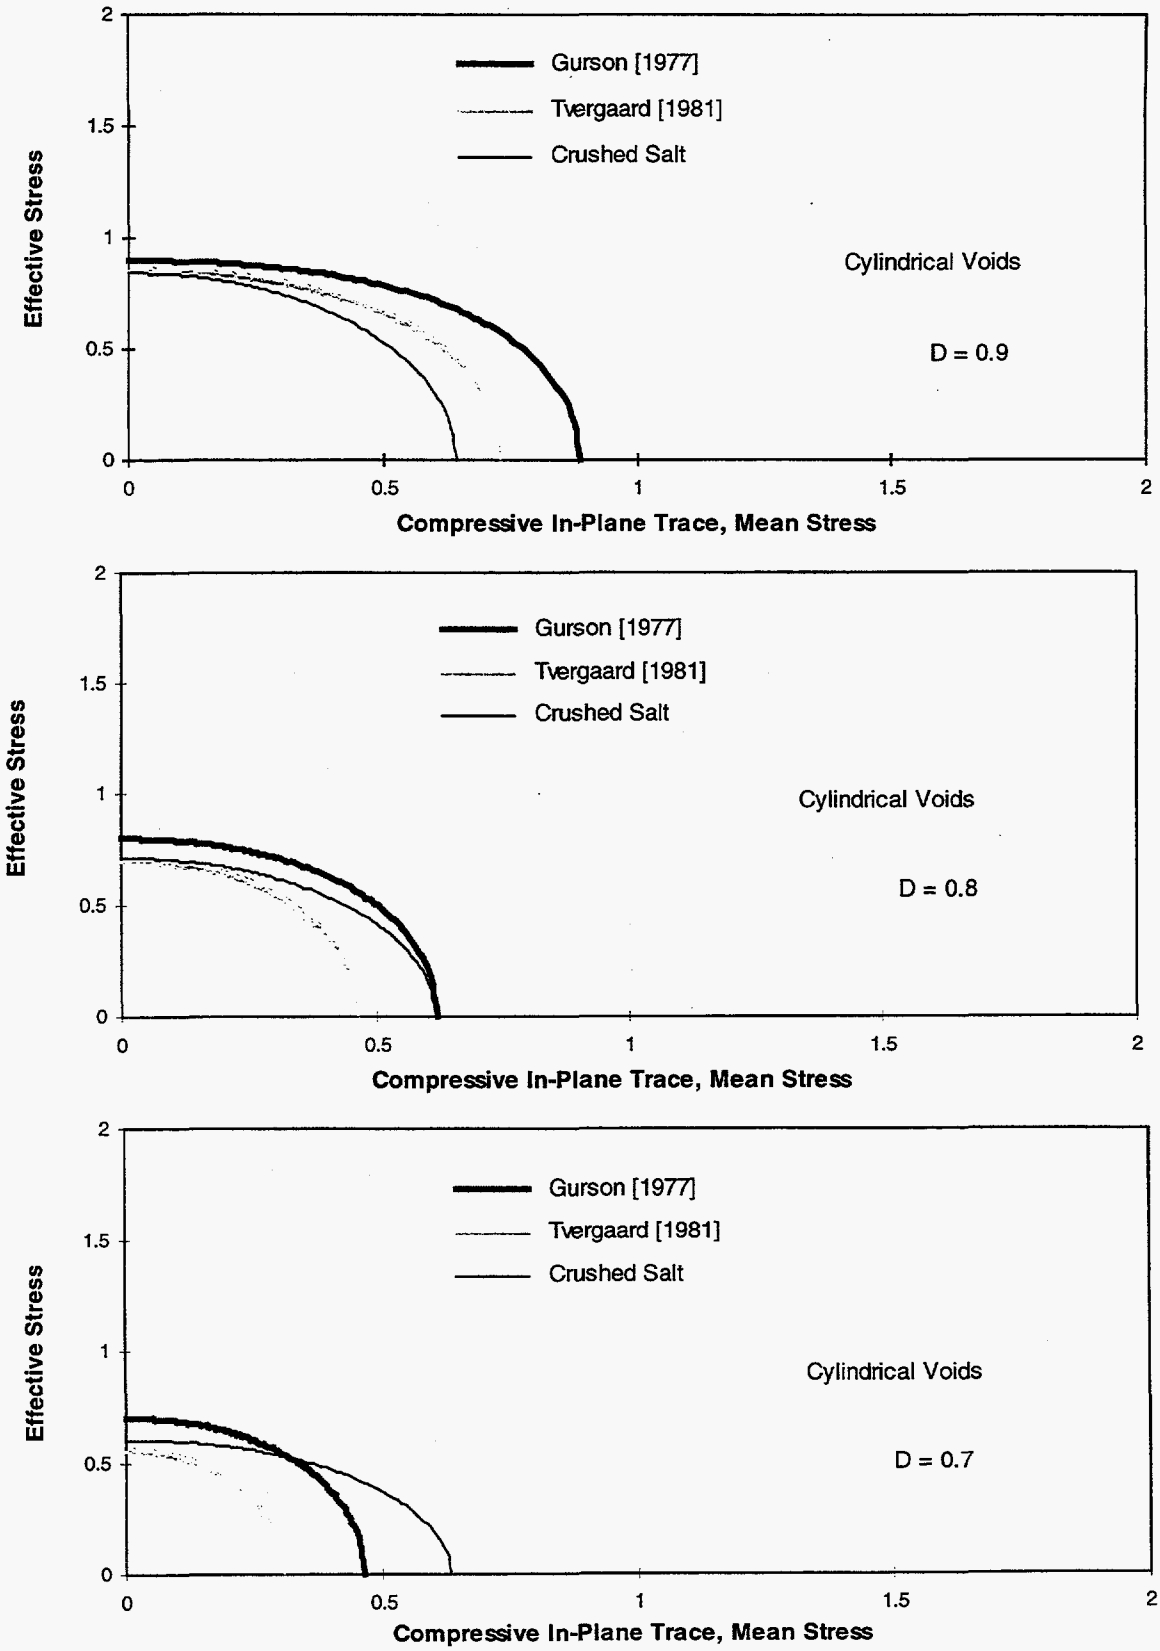

Figure 5-2. Comparison of the crushed-salt model to Gurson's and Tvergaard's models, assuming long, circular, cylindrical voids.

the calculations and equation forms suggested by others, they formulated an elliptic potential function to describe the porous material, which may be written as:

$$F_{sm} = \left[\left(\frac{(1 - D)m}{\left(1 - (1 - D)^{1/m}\right)^m} \right)^{\frac{2}{m+1}} \left(\frac{3\sigma_m}{2m} \right)^2 + \left(\frac{2 - D}{D} \right)^{\frac{2m}{m+1}} \left(3J_2\right) \right]^{1/2} \tag{5-7}$$

where m is the effective stress exponent for the creep power law. To compare Equations 5-2 and 5-7, contours are computed where the potential functions are equal to one. As for the comparison to the Gurson and Tvergaard models, a triaxial compression test is assumed and the stress differences are computed for values of mean stress. Thus Equations 5-2 and 5-7 are rewritten as:

$$\Delta\sigma_{cs} = \left[\frac{1}{\kappa_2} \left(\frac{2 - D}{D} \right)^{\frac{-2n}{n+1}} \left(-\kappa_0 \, \Omega^{\kappa_1} \sigma_m^2 + 1 \right) \right]^{1/2}$$

$$\Delta\sigma_{sm} = \left\{ \left(\frac{2 - D}{D} \right)^{\frac{-2m}{m+1}} \left[- \left(\frac{(1 - D)m}{\left[1 - (1 - D)^{1/m}\right]^m} \right)^{\frac{2}{m+1}} \left(\frac{3\sigma_m}{2m} \right)^2 + 1 \right] \right\}^{1/2} \tag{5-8}$$

The crushed-salt model parameters given in Chapter 4 are used for the crushed-salt model, and the exponent m in Sofronis and McMeeking's model was assumed to be equal to n. Figure 5-3 contains compressive stress space plots that compare the crushed-salt potential to the one presented by Sofronis and McMeeking (1992). Despite the subtle differences between the crushed salt and Sofronis and McMeeking potential functions, Figure 5-3 shows significant differences in their contours. Comparison of Figure 5-3 to Figure 5-1 shows that Sofronis and McMeeking's model compares closely with Gurson's spherical void model.

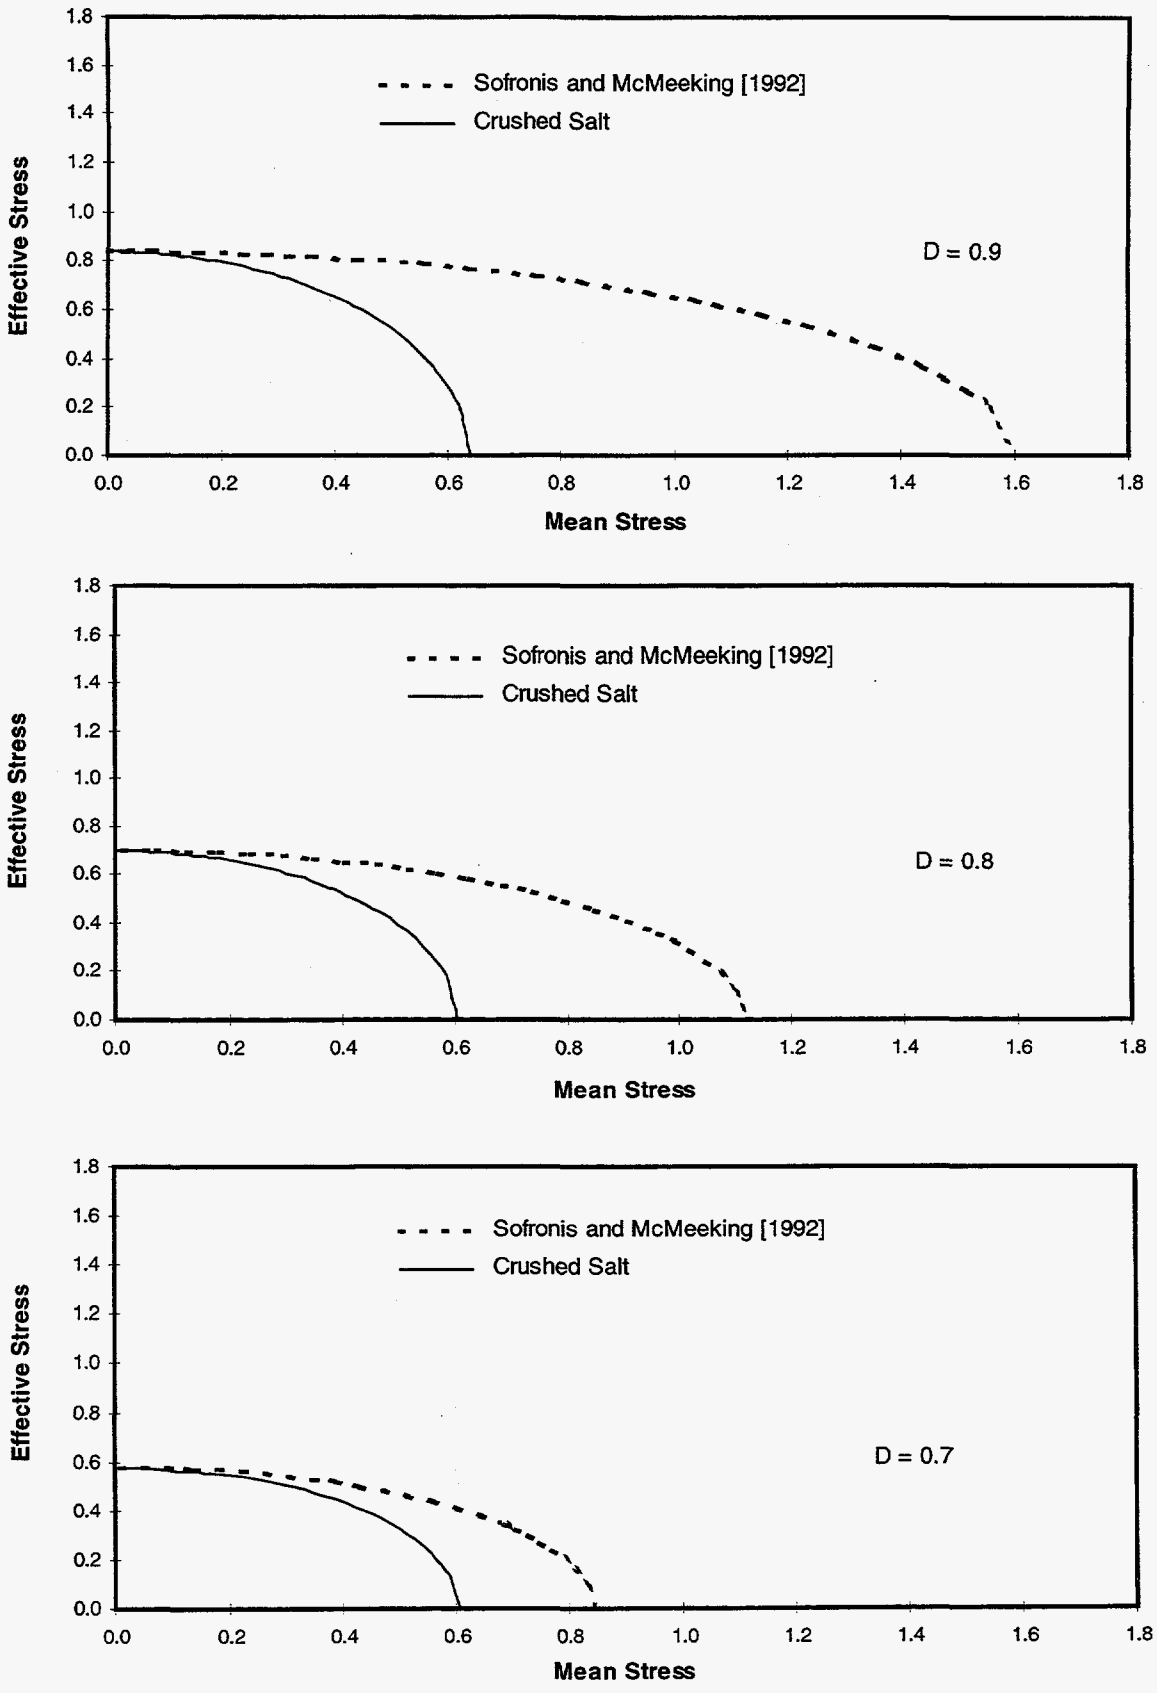

Figure 5-3. Comparison of the crushed-salt model to Sofronis and McMeeking's model.

6.0 OTHER MODEL CONSIDERATIONS

During the course of this study, various functional forms addressing specific parts of the constitutive model were developed in an effort to improve the constitutive model. Model improvement was judged by fitting the experimental database and observing changes in the goodness of fit. These investigations mainly involved the moisture function and the flow potential, which are discussed in the remainder of this chapter.

6.1 Moisture Function

Many researchers (e.g., Pfeifle and Senseny [1985], Holcomb and Shields [1987], Yost and Aronson [1987], Fordham [1988], Spiers et al. [1989], Zeuch and Holcomb [1991], Zeuch et al. [1991], and Wang et al. [1992]) have found that the addition of a small amount of moisture significantly increases the consolidation rate of crushed salt. In addition, there appears to be a quantity of moisture above which further increases in the consolidation rate are not noticeable. However, the amount of moisture producing the largest consolidation rate may vary depending on temperature and pressure. When a significant amount of moisture is available, a retardation in the consolidation rate could occur if the interconnected porosity disappears and the moisture is trapped, leading to the generation of pore pressures. In Chapter 2, the Spiers and Brzesowsky (1993) grain boundary diffusional pressure solutioning model was adapted to represent the increased creep consolidation caused by added moisture. However, during their model development, Spiers and Brzesowsky assumed that the aggregate was flooded with brine. Since an essentially unlimited supply of saturated solution phase was assumed, moisture or brine content does not appear explicitly in their model as a state variable. Therefore, moisture functions were assumed as direct multipliers of the Spiers and Brzesowsky model's predicted effective strain rate to account for varying moisture content. The first functional relationship for moisture effects (M) was taken from Callahan et al. (1995) and is written as:

$$M = 1 - e^{-aw} \tag{6-1}$$

where:

w = moisture fraction by weight

a = material parameter.

Equation 6-1 has a value of zero when the moisture content is zero and asymptotically approaches a value of one as the moisture content increases without bound. The rate at which M approaches the asymptote is governed by parameter a. Equation 6-1 served as a direct multiplier on the equivalent consolidation strain rate contributed by the pressure solutioning portion of the crushed-salt constitutive model. Thus, when the moisture content was zero, only the dislocation creep mechanism contributed to the strain rate, and when the moisture content was nonzero, both the dislocation creep and pressure solutioning mechanisms contributed to the strain rate. When the creep consolidation model was fit to the experimental data, the fitting algorithm produced a large value for parameter a. Thus the function included in Equation 6-1 acted like a Heaviside function, turning the pressure solutioning portion of the model on and off, depending on whether or not a particular specimen was wet or dry. No improvement in the goodness of fit could be achieved by accounting for the moisture variation once moisture was present. In other words, the significant difference between wet and dry specimen deformation is accounted for by the binary nature of the function, but once moisture is present the variation for different moisture contents is not significant. Four potential explanations exist to help understand this behavior:

1. The specimen-to-specimen variability is as great as changes caused by moisture content differences.

2. Moisture content effects are correlated to other test conditions or combinations of test conditions that mask the moisture effects.

3. The test conditions (i.e., the database) are inadequate.

4. The effect of moisture is nearly constant for our range of grain sizes.

The tests included in the database with added moisture are shown in Table 6-1. Thirty-six of the 56 tests in the database were conducted with added moisture. Review of the figures presented in Appendix C shows that specimen-to-specimen variability can be significant. For example, test conditions for Tests CS7 and CS8 (Figures C-7 and C-8) are nearly the same, yet their strain rates and deformation are quite different.

Table 3-2 showed the mean grain size for each of the tests in the database. As noted in the table footnote, the grain size was estimated for four tests. For the remaining tests, the grain size was measured using standard sieve analysis. Also of significance is the fact that six of the tests were performed on dynamically compacted crushed-salt specimens. Tests SC10 and SC11 were performed on field samples from the large-scale dynamic compaction tests. Tests RS/DCCS/1, RS/DCCS/3, RS/DCCS/4, and RS/DCCS/5 were performed on laboratory samples from the small-scale dynamic compaction tests. The remaining tests were performed on mine-run salt, with the loads applied quasi-statically.

Table 6-1. Hydrostatic and Shear Consolidation Tests Conducted with Added Moisture

(a) Saturated tests moisture content computed from initial void ratio.

(b) Grain size for the dynamically compacted specimens is an estimate.

In the model fitting performed in this study, the consolidation rate was not assumed to be dependent on the type of loading used to preconsolidate the crushed salt. However, recent microscopic analysis has suggested that the consolidation rate is greatly enhanced in the dynamic compaction process. Furthermore this analysis has revealed that the deformation is localized to zones where the grain size is much smaller in comparison to the mean grain size reported: i.e., approximately 2–5 microns for the large-scale compaction test and 20 microns for the small-scale compaction tests. These zones are located along the "lift planes" where the material has been pulverized because of the localized dynamic effort used to compact the crushed salt. The conclusion of this microscopy is that the global functional form that defines the grain-size dependence used in the current model fit may not be appropriate because the deformation is localized. However, this information was not available at the time this study was initiated.

Figures 6-1, 6-2, and 6-3 plot moisture content versus average grain size, compressive mean stress, and stress difference. The saturated tests were not plotted on these figures so that the individual tests could be seen in the range up to 5 percent moisture by weight. These figures illustrate holes in the database but also illustrate that moisture content is not directly correlated to these other variables.

Spiers and Brzesowsky (1993) present data that illustrate the effect of grain size on strain rate in wet aggregates. However, their experiments were conducted on grain sizes about an order of magnitude smaller (0.098 to 0.41 millimeter) than those in the database discussed in Chapter 3. Information presented by Callahan et al. (1995) shows that the strain rates in these larger grain-size tests are quite similar despite the different moisture contents (e.g., see Callahan et al. [1995], Figure 4-9). Based on this information, it appears that moisture content variation in these larger grain sizes is not as important as the smaller grain sizes. However, insufficient data are available to judge where the transition occurs.

Because information could not be collected using Equation 6-1, a different functional form for moisture content was adopted. This form is written as:

$$M = w^{a} \tag{6-2}$$

As in Equation 6-1, Equation 6-2 has a value of zero when the moisture content is zero, but grows as the moisture content increases. The rate at which M increases is governed by parameter a. Equation 6-2 served as a direct multiplier on the equivalent consolidation strain rate contributed by the pressure solutioning portion of the crushed-salt constitutive model. Thus when the moisture content was zero only the dislocation creep mechanism contributed to the strain rate, and when the moisture content was nonzero both the dislocation creep and pressure solutioning mechanisms contributed to the strain rate. Equation 6-2 is the form used in the constitutive model presented in Chapter 2.

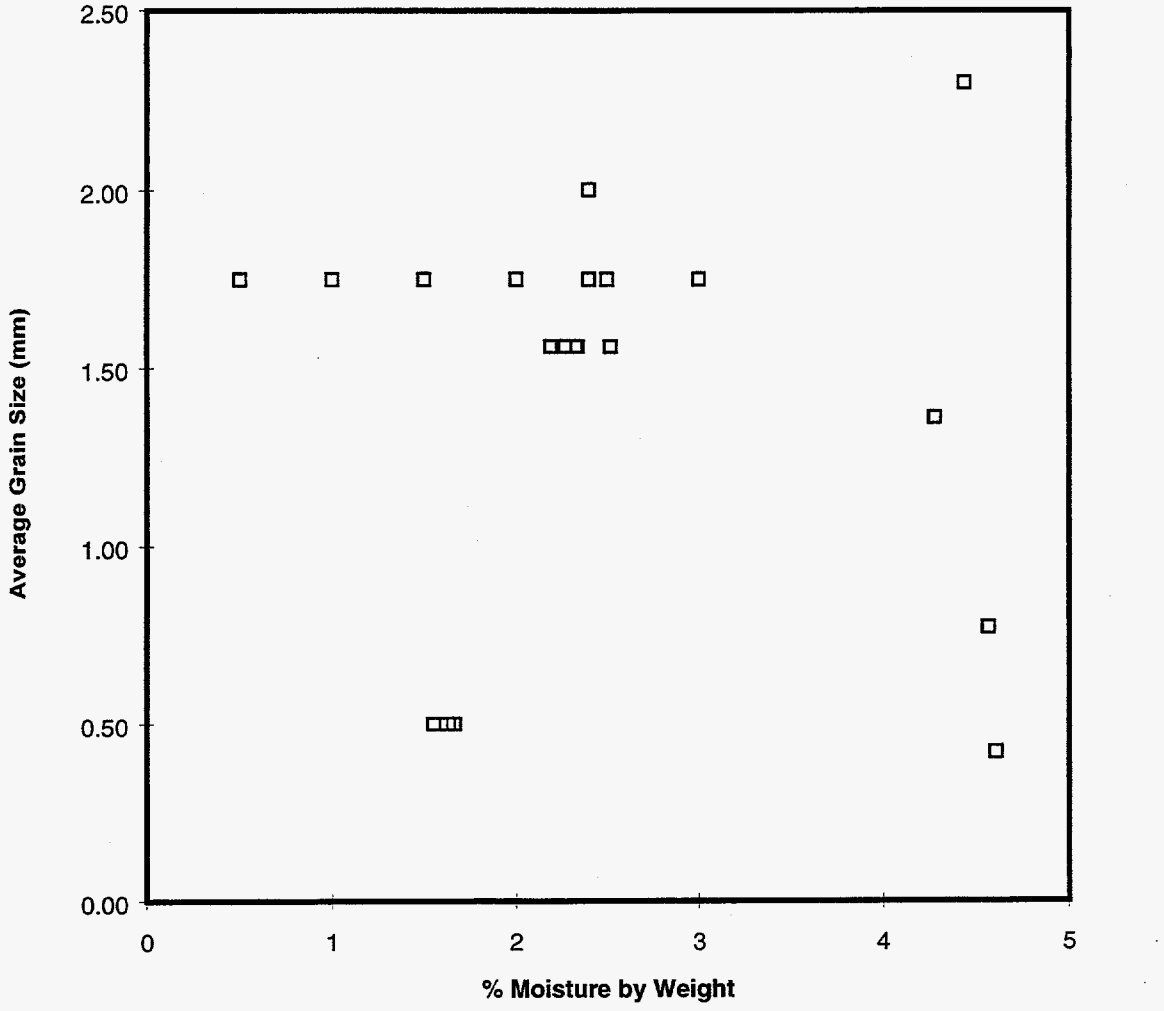

Figure 6-1. Plot of shear and hydrostatic consolidation tests as a function of moisture content and grain size.

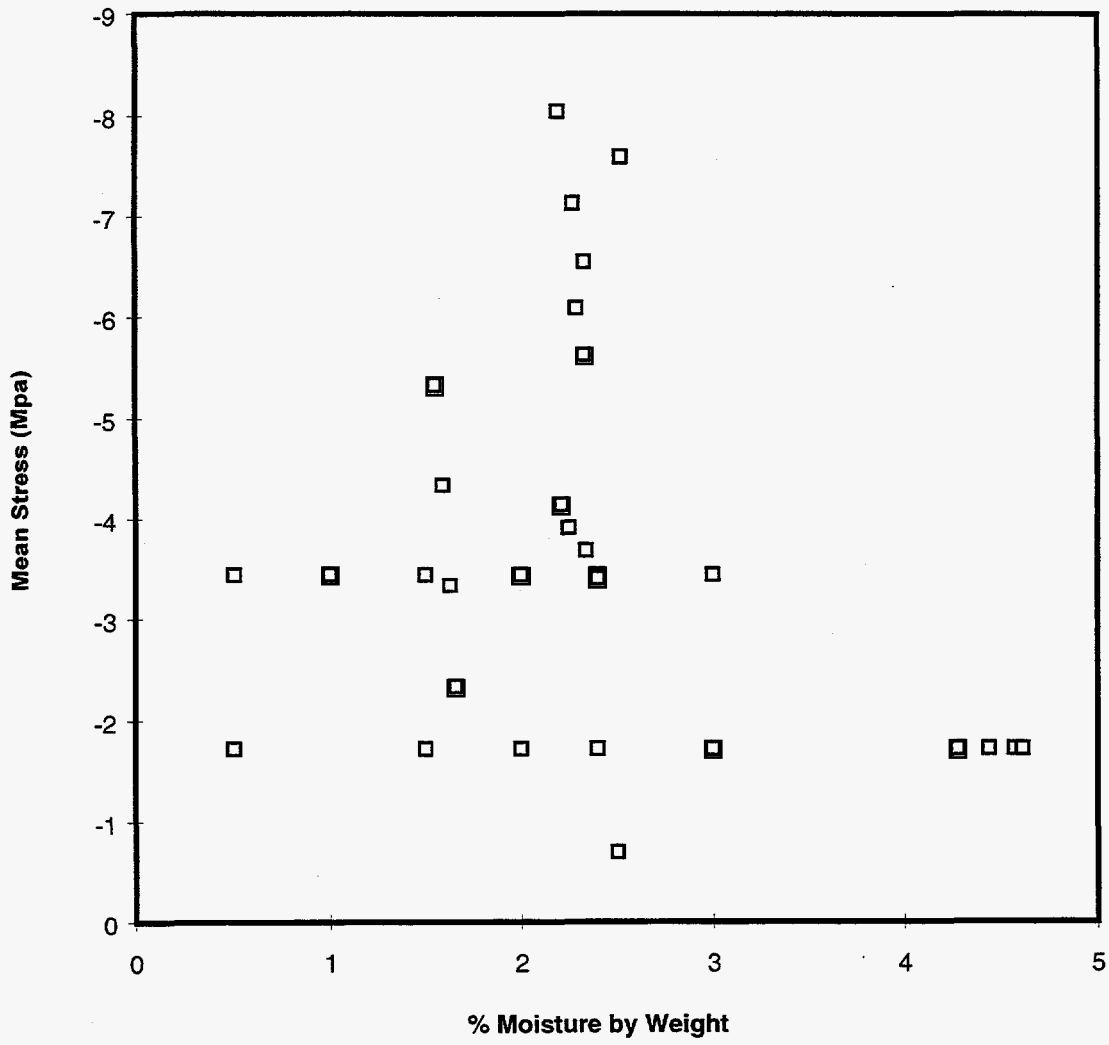

Figure 6-2. Plot of shear and hydrostatic consolidation tests as a function of moisture content and mean stress.

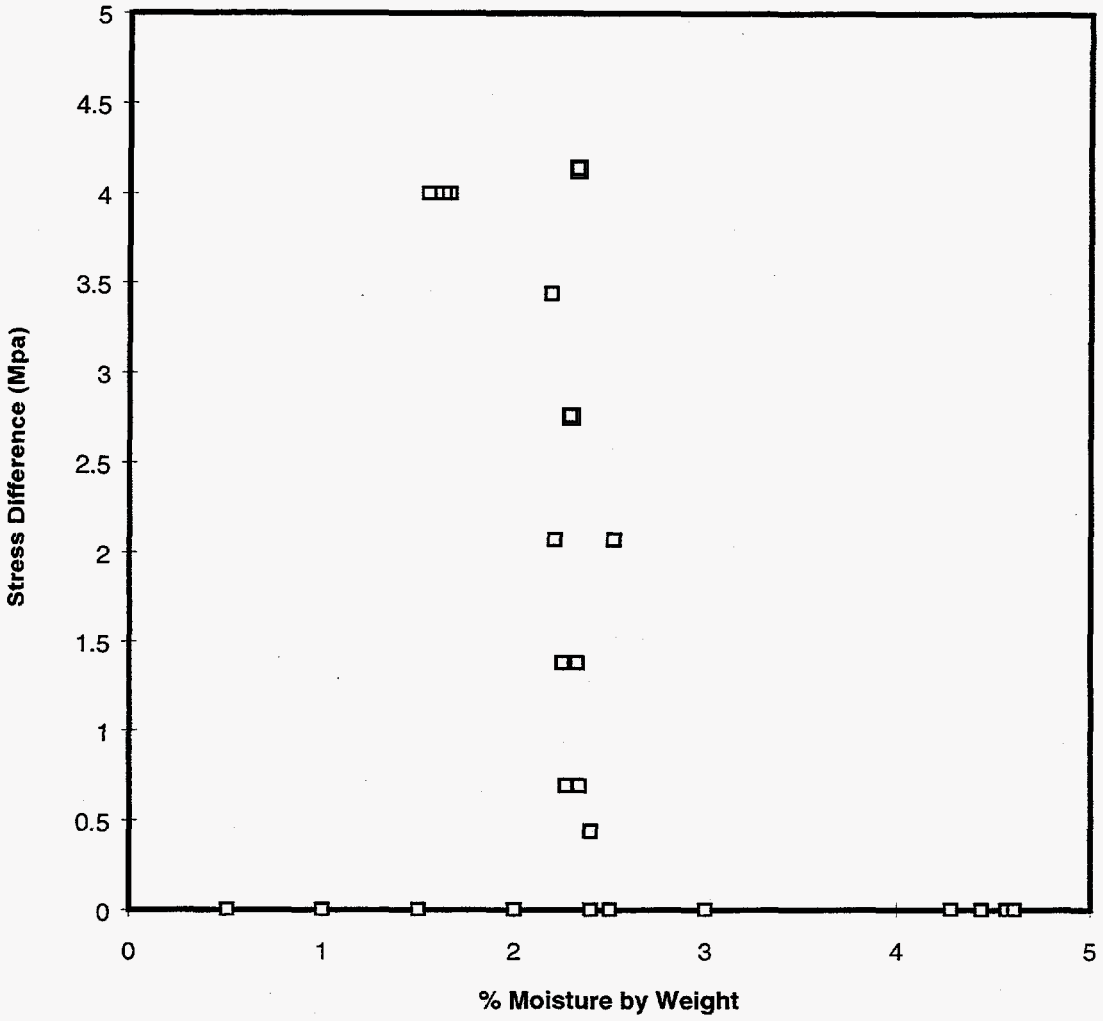

Figure 6-3. Plot of shear and hydrostatic consolidation tests as a function of moisture content and stress difference.

6.2 Flow Potential

Two different attempts were made to improve the goodness of fit for the flow potential. The first attempt involved a change in Ω given in Equation 2-5, which was successful. The second attempt consisted of the consideration of different stages in the densification process, which was not successful. These two modifications to the flow potential are described in the remainder of this section.

The fractional density function, Ω, was originally written as:

$$\Omega = \left[\frac{(1 - D)\, n}{\left[1 - (1 - D)^{1/n}\right]^n} \right]^{\frac{2}{n+1}} \tag{6-3}$$

Comparing Equation 6-3 to Equation 2-5 shows that Equation 2-5 incorporates a transition defined by parameter D_v, whereas Equation 6-3 does not. For fractional density values less than D_v, Equation 2-5 produces a constant value for Ω. The goodness of fit to the lateral-to-axial strain rate ratios (Appendix B) was improved when Equation 2-5 was used; thus this functional form was adopted.

Many researchers consider different stages in the densification process (e.g., Helle et al. [1985]). Usually a fractional density (D) of 0.9 is assumed to be a demarcation between an initial stage and a final stage in the process. The initial stage ($D < 0.9$) is characterized by distinguishable particles densifying by neck growth at the increasing number of contact points. The final stage ($0.9 < D < 1$) is characterized by an array of spherical holes that decrease in size as densification progresses. With these distinctive regions identified and apparently used successfully by others, an attempt was made to improve the flow potential by considering multiple stages in the consolidation process. This was accomplished by considering an initial stage, a transitional stage, and a final stage defined as follows:

$$\begin{aligned} \text{Initial Stage} &= D_0 \le D \le D_s \\ \text{Transitional Stage} &= D_s \le D \le D_t \\ \text{Final Stage} &= D_t \le D \le 1 \end{aligned} \tag{6-4}$$

D_s and D_t are assumed to be parameter values. The transitional zone is included so that a smooth transition occurs between the discontinuous initial and final stages. The effective stress measure for the final stage is assumed to be the same as the effective stress measure given in Equation 2-3. The effective stress measure for the initial stage is assumed to be:

$$\sigma_{eq_1} = \zeta_0 \frac{\sigma_0}{m+1}\left[\Omega_1\left(\frac{|\sigma_m|}{\sigma_0}\right)^{\frac{m+1}{m}} + \left(\frac{2-D}{D}\right)^{\frac{2m}{m+1}}\left(\frac{\sigma_1-\sigma_3}{\sigma_0}\right)^{\frac{m+1}{m}}\right]^m \tag{6-5}$$

where:

$$\Omega_1 = \left(\frac{D_0}{D}\right)^{1/3}\left(\frac{D-D_0}{1-D_0}\right)^{1/2}\left(\frac{1-D}{D^2(D-D_0)}\right)^m \tag{6-6}$$

D_0 = initial fractional density (0.64)

D = current fractional density

σ_m = mean stress = $\frac{\sigma_{kk}}{3}$

σ_3 = minimum principal stress

σ_1 = maximum principal stress

ζ_0, σ_0, and m = material parameters.

Motivation for use of the functional form described by Equation 6-6 comes from Helle et al. (1985). This is the geometrical relationship they used for initial stage densification. This form was also used by Zeuch (1990) for WIPP salt, since he adopted the hot isostatic pressing equations of Helle et al.

In the transition region, the effective stress is:

$$\sigma_{eq}^t = \frac{D_t - D}{D_t - D_s}\sigma_{eq_1} + \frac{D - D_s}{D_t - D_s}\sigma_{eq} \tag{6-7}$$

The flow potential is described by the derivative of the effective stress measure. The derivative in the initial stage is:

$$\frac{\partial \sigma_{eq_1}}{\partial \sigma_{ij}} = \zeta\left\{\alpha_1 \delta_{ij} + \beta_1\left(\left[\frac{\cos 2\psi}{\cos 3\psi}\right]\frac{s_{ij}}{\sqrt{J_2}} + \left[\frac{\sqrt{3}\sin\psi}{J_2\cos 3\psi}\right] t_{ij}\right)\right\} \tag{6-8}$$

where:

$$\zeta = (\zeta_0)^{1/m}\left(\frac{\sigma_0}{m+1}\right)^{\frac{1-m}{m}}\left(\sigma_{eq_1}\right)^{\frac{m-1}{m}}$$

$$\alpha_1 = \frac{\Omega_1 \operatorname{sgn}(\sigma_m)}{3}\left|\frac{\sigma_m}{\sigma_0}\right|^{1/m} \tag{6-9}$$

$$\beta_1 = \left[\frac{2-D}{D}\right]^{\frac{2m}{m+1}}\left(\frac{2\sqrt{J_2}\cos\psi}{\sigma_0}\right)^{1/m}$$

Equation 6-8 is seen to be undefined as the Lode angle approaches $\pm\pi/6$. In other words, the flow potential forms corners at $\psi = \pm\pi/6$, and the direction of straining is not unique. To eliminate this problem computationally, the flow potentials on either side of the corner are averaged, which produces an indeterminant form that is examined in the limit as $\psi \rightarrow \pm\pi/6$. Performing this limiting operation, Equation 6-8 becomes:

$$\frac{\partial \sigma_{eq_1}}{\partial \sigma_{ij}} = \zeta\left\{\alpha_1 \delta_{ij} + \beta_1\left(\frac{s_{ij}}{\sqrt{3J_2}} \mp \frac{t_{ij}}{2J_2}\right)\right\} \tag{6-10}$$

Following the procedure used to compute the lateral-to-axial strain rate ratio outlined in Chapter 2, Equation 6-10 may be used to express the initial stage strain rate ratio for a triaxial compression test as:

$$\mathbf{R}_1 = \frac{\alpha_1 + \frac{\beta_1}{2}}{\alpha_1 - \beta_1} \tag{6-11}$$

In the transition zone, the flow potential is written as:

$$\frac{\partial \sigma^t_{eq_1}}{\partial \sigma_{ij}} = \frac{(D_t - D)}{(D_t - D_s)}\frac{\partial \sigma_{eq_1}}{\partial \sigma_{ij}} + \frac{(D - D_s)}{(D_t - D_s)}\frac{\partial \sigma_{eq}}{\partial \sigma_{ij}} \tag{6-12}$$

Substitution of Equations 6-5 and 2-5 into Equation 6-12 yields:

$$\frac{\partial \sigma^{t}_{eq_1}}{\partial \sigma_{ij}} = \frac{(D_t - D)}{(D_t - D_s)} \zeta \left\{ \alpha_1 \delta_{ij} + \beta_1 \left(\left[\frac{\cos 2\psi}{\cos 3\psi} \right] \frac{s_{ij}}{\sqrt{J_2}} + \left[\frac{\sqrt{3} \sin \psi}{J_2 \cos 3\psi} \right] t_{ij} \right) \right\}$$
$$+ \frac{(D - D_s)}{(D_t - D_s)} \frac{1}{\sigma_{eq}} \left\{ \alpha \delta_{ij} + \beta \left(\left[\frac{\cos 2\psi}{\cos 3\psi} \right] \frac{s_{ij}}{\sqrt{J_2}} + \left[\frac{\sqrt{3} \sin \psi}{J_2 \cos 3\psi} \right] t_{ij} \right) \right\} \tag{6-13}$$

Then, as was done for Equation 6-8 to create Equation 6-10 at the corners, Equation 6-13 becomes:

$$\frac{\partial \sigma^{t}_{eq_1}}{\partial \sigma_{ij}} = \frac{(D_t - D)}{(D_t - D_s)} \zeta \left[\alpha_1 \delta_{ij} + \beta_1 \left(\frac{s_{ij}}{\sqrt{3J_2}} \mp \frac{t_{ij}}{2J_2} \right) \right]$$
$$+ \frac{(D - D_s)}{(D_t - D_s)} \frac{1}{\sigma_{eq}} \left[\alpha \delta_{ij} + \beta \left(\frac{s_{ij}}{\sqrt{3J_2}} \mp \frac{t_{ij}}{2J_2} \right) \right] \tag{6-14}$$

Again, following the procedure used to compute the lateral-to-axial strain rate ratio outlined in Chapter 2, Equation 6-14 may be used to express the transitional stage strain rate ratio for a triaxial compression test as:

$$\mathbf{R}_t = \frac{(D_t - D)\zeta \left(\alpha_1 + \frac{\beta_1}{2} \right) + (D - D_s) \frac{1}{\sigma_{eq}} \left(\alpha + \frac{\beta}{2} \right)}{(D_t - D)\zeta (\alpha_1 - \beta_1) + (D - D_s) \frac{1}{\sigma_{eq}} (\alpha - \beta)} \tag{6-15}$$

Thus Equations 2-20, 6-11, and 6-15 form the equations fitted to the laboratory test data for densification stages described in Equation 6-4. Use of the densification stages did not improve the goodness of fit for the flow potential. Thus the equations as stated in Chapter 2 were retained.

7.0 SUMMARY AND CONCLUSIONS

Crushed salt is planned to be a major long-term component of the shaft seal system at the WIPP. The crushed-salt seal gradually becomes effective as it consolidates over time because of the creep of the surrounding intact salt, which produces shaft closure and loading of the crushed salt. The ability to predict creep consolidation of crushed salt is important to the design and compliance evaluation of WIPP seals. The work reported here represents a continuation of earlier studies devoted to constitutive models for crushed-salt reconsolidation. Understanding the creep consolidation of WIPP crushed salt and our ability to predict its mechanical behavior have been greatly improved as a result of these studies. Crushed-salt consolidation is important in two specific areas:

1. Crushed salt consolidates with time as the intact salt surrounding the shaft creeps inward. This consolidation process resists movement of the surrounding intact salt and produces a load on the shaft surface, which promotes healing of the disturbed rock zone (DRZ) in the salt immediately surrounding the shaft. This healing greatly reduces the DRZ's flow characteristics and helps eliminate this potential pathway.

2. The consolidation of crushed salt reduces the permeability and porosity of the crushed salt itself, greatly enhancing the crushed salt as an effective seal material.

The present study is a continuation of two earlier studies (Callahan et al. [1995], RE/SPEC Inc. [1996], Callahan et al. [1996]). The objectives of the current study were to incorporate the governing deformation mechanisms into a single model and to enhance the database with shear consolidation tests applicable to the operating conditions expected for the dynamically compacted crushed-salt seal material. Before these studies were initiated, the only model used to characterize creep consolidation of WIPP crushed salt was the model proposed by Sjaardema and Krieg (1987).

The first study (Callahan et al. [1995]) identified ten models developed to characterize the deformation of crushed salt. Three of these models were selected for further evaluation. The models were modified to include effects of potentially important parameters such as deviatoric stress, temperature, moisture content, and particle size. The models were generalized to be applicable to three-dimensional states of stress and fit to an assembled database of hydrostatic and shear consolidation tests applicable to the WIPP. The study identified two primary operative mechanisms that contribute to crushed-salt deformation: dislocation creep and grain boundary diffusional pressure solutioning. The first mechanism dominates in dry granular aggregates, whereas the second mechanism is only operative in wet granular aggregates. These mechanisms are included separately in two of the constitutive models evaluated in the first study.

The second study (RE/SPEC Inc. [1996], Callahan et al. [1996]) was conducted to correct deficiencies discovered in the three models. Basically the models were unable to predict a

reversal in the lateral strain rate in a triaxial test. The ability to predict this behavior is a necessary condition for the transition to intact salt behavior as the crushed-salt fractional density approaches one. Unfortunately all tests in the crushed-salt laboratory database assembled in the first study exhibit primarily a positive lateral-to-axial strain rate ratio. Thus the database was biased toward conditions unrepresentative of the anticipated dynamically compacted crushed salt with initial fractional densities near 0.9. Therefore two additional shear consolidation tests with initial fractional densities near 0.8 were conducted and added to the database. The functional form of the flow potential was modified, and the shear consolidation tests were fit to determine material constants for the three crushed-salt consolidation models. The refined model characterizations were found to provide appropriate behavior under uniaxial states of stress, enable a sign reversal of the lateral strain rate, and provide a natural transition to intact salt at complete consolidation. However, predictions of the hydrostatic tests with the models were found to be quite poor.

In this study the creep consolidation model for crushed salt was updated to combine dislocation creep and grain boundary diffusional pressure solutioning into a single constitutive model. The dislocation creep model was adapted from the multimechanism deformation constitutive model (Munson et al. [1989]) used to describe creep deformation of intact salt. The pressure solutioning model was adapted from the densification model for wet salt aggregates presented by Spiers and Brzesowsky (1993). The strain rates from the two contributing mechanisms are additive, with the contribution from the pressure solutioning portion of the model disappearing as the moisture content goes to zero. When the fractional density of the crushed salt reaches one, the model produces intact salt behavior predicted by the multi-mechanism deformation model. Four new laboratory shear consolidation experiments were conducted with fractional densities near the initial fractional density expected in the dynamically compacted crushed-salt seal (approximately 0.9). These tests expand the database into fractional density ranges previously untested and provide information on the crushed-salt flow behavior as its density increases. One test clearly demonstrates the reversal in lateral deformation as the density increases. These tests were added to the experimental database, which was fit to obtain material parameter values for the updated crushed-salt constitutive model. The results of the model fitting produced material parameter values representative of the entire database. Two separate fits were performed. The first fit used only the shear consolidation tests in the database, and the second fit used both the shear and hydrostatic consolidation tests. In our previous studies, dramatic changes in the parameter values were observed when the different tests were fit. In the present study, these separate fits produced similar parameter values, which indicates that the constitutive model is more representative of the physics of the creep consolidation of crushed salt than were the previous models.

As a result of this study, a constitutive model for crushed salt is available that contains the observed mechanisms for crushed-salt consolidation. When consolidation is complete, the model predicts intact salt behavior. The model characterizes the experimental data quite well over a wide range of porosities and stress triaxialities.

APPENDIX A

Input Files to BMDP, Nonlinear Regression Programs 3R and AR

This appendix contains three input files. The first file (FLOW.INP) was the input file to the Program 3R and was used to determine the flow rate parameters. The second and third files (MDSP2.INP and MDSP3.INP) were the input files to the Program AR. The files were used to determine two sets of the creep consolidation parameters fit to the shear consolidation database (MDSP2.INP) and the combined shear and hydrostatic consolidation database (MDSP3.INP).

APPENDIX B

Lateral-to-Axial Strain Rate Ratio Model Fits to the Shear Consolidation Tests

This appendix contains the plots of the model fits to the 16 shear consolidation tests used in determining the flow potential parameters. Each plot shows the measured and predicted lateral-to-axial strain rates ratios as a function of density for each of the 16 tests.

APPENDIX C

C-S Constitutive Model Fits to the Hydrostatic and Shear Consolidation Tests

This appendix contains the plots of the C-S constitutive model fits to the 40 hydrostatic consolidation tests and the 16 shear consolidation tests. The two C-S constitutive model fits are fits to two test databases; namely, (1) a database containing the 16 shear consolidation tests only and (2) a database containing the combined 56 shear and hydrostatic consolidation tests.

The appendix contains 56 figures. Each figure shows the two model fits to each particular laboratory test; either a hydrostatic consolidation test (Figure C-1 through C-40) or a shear consolidation test (Figures C-41 through C-56). The plots labeled "Shear Database" represent the C-S constitutive model fit to the shear test database, and the plots labeled "Combined Database" represent the C-S constitutive model fit to the combined test database.

Hydrogen Data-Panel 3

All samples were sampled at sub-atmospheric pressure and pressurized by the lab as required for analysis; dilution factors included in data set. The MDL (method detection limit) is the sample quantitation limit determined in accordance with 40 CFR Part 136; actual and dilution corrected MDLs included in data set.

8/21/07-7/24/08 MDL = 10.79 ppmv
7/25/08-6/16/09 MDL = 14.93 ppmv
6/17/09-6/8/10 MDL = 15.17 ppmv
6/9/10-12/28/10 MDL = 7.00 ppmv
12/29/10-11/30/11 MDL = 14.03 ppmv
12/1/11-10/21/12 MDL = 14.40 ppmv
10/22/12-? MDL = 17.29 ppmv ← MDL end date not yet determined

Some values in column "Results" are less than dilution corrected MDLs. These values are not included in the statistical evaluation. When results are N.D. (not-detected) or less than dilution corrected MDLs, the values used for the statistical evaluation are 1/2 the corrected MDL.

Methane Data-Panel 3

All samples were sampled at sub-atmospheric pressure and pressurized by the lab as required for analysis; dilution factors included in data set. The MDL (method detection limit) is the sample quantitation limit determined in accordance with 40 CFR Part 136; actual and dilution corrected MDLs included in data set.

8/21/07-7/24/08 MDL = 17.99 ppmv
7/25/08-6/16/09 MDL = 23.74 ppmv
6/17/09-6/8/10 MDL = 22.21 ppmv
6/9/10-12/28/10 MDL = 21.39 ppmv
12/29/10-11/30/11 MDL = 23.97 ppmv
12/1/11-10/21/12 MDL = 17.45 ppmv
10/22/12-? MDL = 15.71 ppmv ← MDL end date not yet determined

Some values in column "Results" are less than dilution corrected MDLs. These values are not included in the statistical evaluation. When results are N.D. (not-detected) or less than dilution corrected MDLs, the values used for the statistical evaluation are 1/2 the corrected MDL.

Methane (CH_4) **CAS# 74-82-8**

Hydrogen Data-Panel 4

All samples were sampled at sub-atmospheric pressure and pressurized by the lab as required for analysis; dilution factors included in data set. The MDL (method detection limit) is the sample quantitation limit determined in accordance with 40 CFR Part 136; actual and dilution corrected MDLs included in data set.

7/25/08-6/16/09 MDL = 14.93 ppmv
6/17/09-6/8/10 MDL = 15.17 ppmv
6/9/10-12/28/10 MDL = 7.00 ppmv
12/29/10-11/30/11 MDL = 14.03 ppmv
12/1/11-10/21/12 MDL = 14.40 ppmv
10/22/12-? MDL = 17.29 ppmv ← MDL end date not yet determined

Some values in column "Results" are less than dilution corrected MDLs. These values are not included in the statistical evaluation. When results are N.D. (not-detected) or less than dilution corrected MDLs, the values used for the statistical evaluation are 1/2 the corrected MDL.

Hydrogen (H_2) **CAS# 1333-74-0**

Methane Data-Panel 4

All samples were sampled at sub-atmospheric pressure and pressurized by the lab as required for analysis; dilution factors included in data set. The MDL (method detection limit) is the sample quantitation limit determined in accordance with 40 CFR Part 136; actual and dilution corrected MDLs included in data set.

7/25/08-6/16/09 MDL = 23.74 ppmv
6/17/09-6/8/10 MDL = 22.21 ppmv
6/9/10-12/28/10 MDL = 21.39 ppmv
12/29/10-11/30/11 MDL = 23.97 ppmv
12/1/11-10/21/12 MDL = 17.45 ppmv
10/22/12-? MDL = 15.71 ppmv ← MDL end date not yet determined

Some values in column "Results" are less than dilution corrected MDLs. These values are not included in the statistical evaluation. When results are N.D. (not-detected) or less than dilution corrected MDLs, the values used for the statistical evaluation are 1/2 the corrected MDL.

Methane (CH_4) **CAS# 74-82-8**

First Edition (*FLAC*^{3D} Version 2.1) April 2002

Second Edition (*FLAC*^{3D} Version 3.0) September 2005

Third Edition (*FLAC*^{3D} Version 3.1) December 2006

Terms and Conditions for Licensing *FLAC^{3D}*

YOU SHOULD READ THE FOLLOWING TERMS AND CONDITIONS CAREFULLY BEFORE USING THE *FLAC^{3D}* PROGRAM. INSTALLATION OF THE *FLAC^{3D}* PROGRAM INTO YOUR COMPUTER INDICATES YOUR ACCEPTANCE OF THESE TERMS AND CONDITIONS. IF YOU DO NOT AGREE WITH THEM, YOU SHOULD RETURN THE PACKAGE PROMPTLY AND YOUR MONEY WILL BE REFUNDED.

This program is provided by Itasca Consulting Group, Inc. Title to the media on which the program is recorded and to the documentation in support thereof is transferred to the customer, but title to the program is retained by Itasca. You assume responsibility for the selection of the program to achieve your intended results and for the installation of the program, the use of and the results obtained from the program.

LICENSE

1. All Itasca codes (with the exception of Student Licenses) are software-locked and require a hardware key to operate the code.
2. You may copy the program for back-up only in support of such use.
3. You may ***not*** use, copy, modify or transfer the program, or any copy, in whole or part, except as expressly provided in this document.
4. You may ***not*** sell, sub-license, rent or lease this program.
5. Licenses are not transferable.

TERMS

The license is effective until terminated. You may terminate it any time by destroying the program together with any back-up copies and returning the hardware lock. It will also terminate if you fail to comply with any term or condition of this agreement. You agree upon such termination to destroy the program together with any back-up copies, modifications, and/or merged portions in any form and return the hardware lock to Itasca.

WARRANTY

Itasca will correct any errors in the code at no charge for twelve (12) months after the purchase date of the code. Notification of a suspected error must be made in writing, with a complete listing of the input and output files and description of the error. If, in the judgment of Itasca, the code does contain an error, Itasca will (at its option) correct or replace the copy at no cost to the user or refund the initial purchase price of the code.

LIMITATION OF LIABILITY

Itasca assumes no liability whatsoever with respect to any use of *FLAC3D* or any portion thereof or with respect to any damages or losses that may result from such use, including (without limitation) loss of time, money or goodwill that may arise from the use of *FLAC3D* (including any modifications or updates that may follow). In no event shall Itasca be responsible for any indirect, special, incidental or consequential damages arising from use of *FLAC3D*.

CODE SUPPORT

Itasca will provide email and telephone support, at no charge, to assist the code owner in the installation of the code on the owner's computer system. Additionally, general assistance may be provided to aid the owner in understanding the capabilities of the various features of the program. However, no-cost assistance is ***not*** provided for help in applying Itasca Software to specific user-defined problems.

Technical support covering modeling questions, applications, definitions, interpretation of results, design guidelines, etc. can be purchased on an as-needed basis. For users who need substantial amounts of assistance, consulting support is available. In all instances, the user is encouraged to send the problem description to Itasca by fax or electronic mail in order to minimize the amount of time spent trying to define the problem.

Itasca reserves the right to determine what qualifies as no-cost assistance and what requires payment.

PRECIS

This volume is the user's guide to *FLAC3D*. This guide contains general information on the operation of *FLAC3D* for engineering mechanics computation.

Section 1 gives an introduction to the capabilities and applications of *FLAC3D*. An overview of the new features in the latest version of *FLAC3D* is also provided.

The first-time user should consult Section 2 for an introduction to the operation of *FLAC3D*. The installation and operation procedures are given along with a simple tutorial to guide the new user through a *FLAC3D* analysis.

Section 3 provides general guidance in the use of *FLAC3D* in problem solving for static mechanical analysis for geotechnical engineering.

An introduction to the built-in programming language, *FISH*, is given in Section 4. This includes a tutorial on the use of the *FISH* language. Note that no programming experience is assumed.

Various items of interest to *FLAC3D* users are contained in Section 5, including a *FLAC3D* run-time benchmark on several different types of computers and procedures for reporting errors and requesting technical assistance.

Section 6 contains a bibliography of published papers describing some applications of *FLAC3D* in different fields of engineering.

The *FLAC3D* Manual consists of ten documents. The following list of volumes, which comprise the *FLAC3D* Manual, are available. (The titles in parentheses below are the names used to refer to the volumes in the text.)

USER'S GUIDE — (User's Guide) — an introduction to *FLAC3D* and its capabilities

COMMAND REFERENCE — (Command Reference) — descriptions of all *FLAC3D* commands

FISH in FLAC3D — (FISH volume) — a complete guide to *FISH* as applied in *FLAC3D*

THEORY AND BACKGROUND — (Theory and Background) — thorough discussions of the built-in features in *FLAC3D*

FLUID-MECHANICAL INTERACTION — (Fluid-Mechanical Interaction) — discussion of the formulation and examples of the groundwater flow model

STRUCTURAL ELEMENTS — (Structural Elements) — descriptions for the six types of structural elements in *FLAC3D*: beams, cables, piles, shells, liners and geogrids

OPTIONAL FEATURES — (Optional Features) — detailed descriptions of the optional features: thermal analysis, creep models, dynamic analysis and C++ user-defined models.

HEXAHEDRAL-MESHING PREPROCESSOR — 3DShop — (3DShop) — a user's guide for *3DShop*, a hexahedral-meshing preprocessor for *FLAC3D*.

VERIFICATION PROBLEMS — (Verifications volume) — a collection of verification problems

EXAMPLE APPLICATIONS — (Examples volume) — a collection of example applications

TABLE OF CONTENTS

1 INTRODUCTION

1.1 Overview . . . . . 1 - 1
1.2 Comparison with Other Methods . . . . . 1 - 3
1.3 General Features . . . . . 1 - 4
1.3.1 Basic Features . . . . . 1 - 4
1.3.2 Optional Features . . . . . 1 - 6
1.3.3 Modeling Physical Processes and Interactions . . . . . 1 - 7
1.4 Summary of Updates from Version 3.0 . . . . . 1 - 9
1.4.1 Parallel Processing on Multiprocessor Computers . . . . . 1 - 9
1.4.2 64-Bit Version . . . . . 1 - 9
1.4.3 Embedded Liner . . . . . 1 - 9
1.4.4 Two-Dimensional Grid Extrusion Tool . . . . . 1 - 10
1.4.5 Nodal Mixed Discretization . . . . . 1 - 10
1.4.6 Built-in Help . . . . . 1 - 10
1.4.7 New Features in ***FISH*** . . . . . 1 - 10
1.4.8 New Commands . . . . . 1 - 11
1.4.9 Revised Example Applications . . . . . 1 - 12
1.5 Fields of Application . . . . . 1 - 13
1.6 Guide to the ***FLAC3D*** Manual . . . . . 1 - 14
1.7 Itasca Consulting Group, Inc. . . . . 1 - 18
1.8 User Support . . . . . 1 - 19
1.9 References . . . . . 1 - 20

2 GETTING STARTED

2.1 Installation and Start-up Procedures . . . . . 2 - 3
2.1.1 System Requirements . . . . . 2 - 3
2.1.2 Installation of ***FLAC3D*** . . . . . 2 - 4
2.1.3 Components of ***FLAC3D*** . . . . . 2 - 4
2.1.4 Utility Software and Graphics Devices . . . . . 2 - 5
2.1.5 Start-up . . . . . 2 - 5
2.1.6 Version Identification . . . . . 2 - 7
2.1.7 Program Initialization . . . . . 2 - 7
2.1.8 Running ***FLAC3D*** . . . . . 2 - 8
2.1.9 Installation Tests . . . . . 2 - 8
2.2 A Simple Tutorial — Use of Common Commands . . . . . 2 - 11
2.3 Nomenclature . . . . . 2 - 22

2.4 The Finite Difference Grid . . . . . 2 - 26
2.5 Command Syntax . . . . . 2 - 27
2.6 Named Objects . . . . . 2 - 29
2.6.1 Macro Object . . . . . 2 - 29
2.6.2 Model Object . . . . . 2 - 30
2.6.3 General Advice . . . . . 2 - 32
2.7 Mechanics of Using ***FLAC3D*** . . . . . 2 - 35
2.7.1 Simple Grid Generation . . . . . 2 - 37
2.7.2 Assigning Material Models . . . . . 2 - 42
2.7.3 Applying Boundary and Initial Conditions . . . . . 2 - 45
2.7.4 Stepping to Initial Equilibrium . . . . . 2 - 50
2.7.5 Performing Alterations . . . . . 2 - 55
2.7.6 Saving/Restoring the Problem State . . . . . 2 - 57
2.7.7 Summary of Commands for Simple Analysis . . . . . 2 - 61
2.8 Sign Conventions . . . . . 2 - 63
2.9 Systems of Units . . . . . 2 - 65
2.10 Precision Limits . . . . . 2 - 66
2.11 Files . . . . . 2 - 67
2.12 Introducing the ***FLAC3D*** Graphical User Interface . . . . . 2 - 70
2.13 References . . . . . 2 - 76

3 PROBLEM SOLVING WITH *FLAC3D*

3.1 General Approach . . . . . 3 - 2
3.1.1 Step 1: Define the Objectives for the Model Analysis . . . . . 3 - 3
3.1.2 Step 2: Create a Conceptual Picture of the Physical System . . . . . 3 - 3
3.1.3 Step 3: Construct and Run Simple Idealized Models . . . . . 3 - 4
3.1.4 Step 4: Assemble Problem-Specific Data . . . . . 3 - 4
3.1.5 Step 5: Prepare a Series of Detailed Model Runs . . . . . 3 - 4
3.1.6 Step 6: Perform the Model Calculations . . . . . 3 - 5
3.1.7 Step 7: Present Results for Interpretation . . . . . 3 - 5
3.2 Grid Generation . . . . . 3 - 6
3.2.1 Overview of the Grid Generator . . . . . 3 - 6
3.2.1.1 Zone Generation . . . . . 3 - 7
3.2.1.2 Connecting Adjoining Primitive Shapes . . . . . 3 - 12
3.2.2 Fitting the Grid to Simple Shapes . . . . . 3 - 15
3.2.3 Grid Generation with ***FISH*** . . . . . 3 - 19
3.2.4 Grid-Extrusion Tool . . . . . 3 - 22

3.3 Boundary Conditions . . . . . 3 - 27
3.3.1 Stress Boundary . . . . . 3 - 27
3.3.1.1 Applied Stress Gradients . . . . . 3 - 29
3.3.1.2 Changing Boundary Stress . . . . . 3 - 30
3.3.1.3 Cautions and Advice . . . . . 3 - 36
3.3.2 Displacement Boundary . . . . . 3 - 39
3.3.3 Real Boundaries — Choosing the Right Type . . . . . 3 - 44
3.3.4 Artificial Boundaries . . . . . 3 - 45
3.3.4.1 Symmetry Planes . . . . . 3 - 45
3.3.4.2 Boundary Truncation . . . . . 3 - 45
3.4 Initial Conditions . . . . . 3 - 46
3.4.1 Uniform Stresses — No Gravity . . . . . 3 - 46
3.4.2 Stresses with Gradients — Uniform Material . . . . . 3 - 47
3.4.3 Stresses with Gradients — Nonuniform Material . . . . . 3 - 48
3.4.4 Stress Initialization in a Nonuniform Grid . . . . . 3 - 49
3.4.5 Compaction within a Nonuniform Grid . . . . . 3 - 52
3.4.6 Initial Stresses following a Model Change . . . . . 3 - 55
3.4.7 Stress and Pore-Pressure Initialization with a Phreatic Surface . . . . . 3 - 56
3.4.8 Initialization of Velocities . . . . . 3 - 59
3.5 Loading and Sequential Modeling . . . . . 3 - 60
3.6 Choice of Constitutive Model . . . . . 3 - 67
3.6.1 Overview of Constitutive Models . . . . . 3 - 67
3.6.2 Selection of an Appropriate Model . . . . . 3 - 71
3.6.3 The Effect of Water . . . . . 3 - 74
3.6.4 Ways to Implement Constitutive Models . . . . . 3 - 75
3.7 Material Properties . . . . . 3 - 76
3.7.1 Mass Density . . . . . 3 - 76
3.7.2 Intrinsic Deformability Properties . . . . . 3 - 77
3.7.3 Intrinsic Strength Properties . . . . . 3 - 80
3.7.4 Post-Failure Properties . . . . . 3 - 83
3.7.4.1 Shear Dilatancy . . . . . 3 - 83
3.7.4.2 Shear Hardening/Softening . . . . . 3 - 85
3.7.4.3 Volumetric Hardening/Softening . . . . . 3 - 89
3.7.4.4 Tensile Softening . . . . . 3 - 89
3.7.4.5 Volume-Pressure Properties . . . . . 3 - 92
3.7.5 Extrapolation to Field-Scale Properties . . . . . 3 - 92
3.7.6 Spatial Variation and Randomness of Property Distribution . . . . . 3 - 99
3.8 Tips and Advice . . . . . 3 - 100

3.9 Interpretation . . . . . 3 - 108
3.9.1 Unbalanced Force . . . . . 3 - 108
3.9.2 Gridpoint Velocities . . . . . 3 - 108
3.9.3 Plastic Indicators . . . . . 3 - 109
3.9.4 Histories . . . . . 3 - 110
3.10 Modeling Methodology . . . . . 3 - 111
3.10.1 Modeling of Data-Limited Systems . . . . . 3 - 111
3.10.2 Modeling of Chaotic Systems . . . . . 3 - 111
3.10.3 Localization, Physical Instability and Path-Dependence . . . . . 3 - 113
3.11 References . . . . . 3 - 115

4 *FISH* BEGINNER'S GUIDE
4.1 Introduction . . . . . 4 - 1
4.2 Tutorial . . . . . 4 - 2

5 MISCELLANEOUS
5.1 ***FLAC3D*** Runtime Benchmark . . . . . 5 - 1
5.2 Error Reporting . . . . . 5 - 3
5.2.1 Reporting via the Internet . . . . . 5 - 3
5.2.2 Reporting via Fax . . . . . 5 - 3
5.3 Technical Support Service . . . . . 5 - 3

EXAMPLES

Example 2.1 ***FLAC3D*** output from "TEST1.DAT" . . . . . 2 - 9
Example 2.2 Creating and using a plot view . . . . . 2 - 11
Example 2.3 Specifying view parameters . . . . . 2 - 13
Example 2.4 Using macros . . . . . 2 - 29
Example 2.5 Using line continuations . . . . . 2 - 30
Example 2.6 Using a named model object . . . . . 2 - 31
Example 2.7 Illustrating the behavior of **RANGE**, **GROUP** and **MACRO** model objects . . . 2 - 31
Example 2.8 Using macros . . . . . 2 - 32
Example 2.9 Creating new commands . . . . . 2 - 33
Example 2.10 Using different object types to do the same job . . . . . 2 - 33
Example 2.11 Creating named ranges . . . . . 2 - 34
Example 2.12 Generating a simple brick element . . . . . 2 - 37
Example 2.13 Using actual coordinates . . . . . 2 - 38
Example 2.14 A sloping surface at the top of a mesh . . . . . 2 - 39
Example 2.15 Combining a regular and a radially graded mesh . . . . . 2 - 39
Example 2.16 Combining **GEN** commands . . . . . 2 - 40
Example 2.17 Creating a model by reflecting elements on planes of symmetry . . . . . 2 - 42
Example 2.18 Assigning different material models in different areas of a single grid . . . . 2 - 44
Example 2.19 Creating and using a named range . . . . . 2 - 44
Example 2.20 Trench problem — quarter-symmetry model . . . . . 2 - 49
Example 2.21 Stepping to initial equilibrium . . . . . 2 - 51
Example 2.22 Excavating the trench and monitoring the response . . . . . 2 - 55
Example 2.23 Trench problem — excavation in stages and support . . . . . 2 - 57
Example 2.24 Using comments during model testing . . . . . 2 - 73
Example 2.25 The GUI tutorial file "TRENCH1.DAT" . . . . . 2 - 74
Example 3.1 Building a horseshoe-shaped tunnel — half model . . . . . 3 - 10
Example 3.2 Building a horseshoe-shaped tunnel — full model . . . . . 3 - 11
Example 3.3 Two unequal sub-grids . . . . . 3 - 13
Example 3.4 A single grid for comparison to two sub-grids . . . . . 3 - 13
Example 3.5 Creating a grid for two tunnels with the same invert elevation . . . . . 3 - 15
Example 3.6 Creating a liner in the service tunnel . . . . . 3 - 17
Example 3.7 Creating the boundary grid . . . . . 3 - 18
Example 3.8 Parameters to create a radially graded mesh around a spherical cavity . . . . 3 - 19
Example 3.9 ***FISH*** function to position gridpoints for a mesh around a spherical shape 3 - 19
Example 3.10 Applying a normal stress to a dipping boundary . . . . . 3 - 28
Example 3.11 Apply changing stress boundary with a ***FISH*** function . . . . . 3 - 30
Example 3.12 Apply changing stress boundary with a ***FISH*** history . . . . . 3 - 31
Example 3.13 Apply changing stress boundary with a table history . . . . . 3 - 31

Example 3.14 Gradual excavation of a circular tunnel . . . . . 3 - 32
Example 3.15 Gradual excavation of a circular tunnel using "ZONK3D.FIS" . . . . . 3 - 33
Example 3.16 "ZONK3D.FIS" . . . . . 3 - 34
Example 3.17 Spin when grid is not in equilibrium . . . . . 3 - 36
Example 3.18 Uplift when material is removed . . . . . 3 - 38
Example 3.19 Applying normal velocities at corners . . . . . 3 - 40
Example 3.20 Applying local axes velocities along model edges . . . . . 3 - 41
Example 3.21 Rotating retaining wall . . . . . 3 - 43
Example 3.22 Initial and boundary stresses in equilibrium . . . . . 3 - 47
Example 3.23 Initial stress state with gravitational gradient . . . . . 3 - 47
Example 3.24 Initial stress gradient in a nonuniform material . . . . . 3 - 48
Example 3.25 Initial stress state for a nonuniform grid . . . . . 3 - 49
Example 3.26 Initial stress state for an irregular free surface . . . . . 3 - 50
Example 3.27 Nonuniform stress initialized in nonuniform grid . . . . . 3 - 52
Example 3.28 Initial stresses following a model change . . . . . 3 - 55

1 INTRODUCTION

1.1 Overview

FLAC3D is a three-dimensional explicit finite-difference program for engineering mechanics computation. The basis for this program is the well-established numerical formulation used by our two-dimensional program, *FLAC*.* *FLAC3D* extends the analysis capability of *FLAC* into three dimensions, simulating the behavior of three-dimensional structures built of soil, rock or other materials that undergo plastic flow when their yield limits are reached. Materials are represented by polyhedral elements within a three-dimensional grid that is adjusted by the user to fit the shape of the object to be modeled. Each element behaves according to a prescribed linear or nonlinear stress/strain law in response to applied forces or boundary restraints. The material can yield and flow, and the grid can deform (in large-strain mode) and move with the material that is represented. The explicit, Lagrangian calculation scheme and the mixed-discretization zoning technique used in *FLAC3D* ensure that plastic collapse and flow are modeled very accurately. Because no matrices are formed, large three-dimensional calculations can be made without excessive memory requirements. The drawbacks of the explicit formulation (i.e., small timestep limitation and the question of required damping) are overcome by automatic inertia scaling and automatic damping that does not influence the mode of failure. *FLAC3D* offers an ideal analysis tool for solution of three-dimensional problems in geotechnical engineering.

FLAC3D is designed specifically to operate on Microsoft Windows systems, and is currently supported on Windows 2000 and Windows XP (including XP64). Itanium-based systems are not supported. Calculations on realistically sized three-dimensional models in geo-engineering can be made in a reasonable time period. For example, a model containing 125,000 zones of a Mohr-Coulomb material can be generated within 350 MB RAM. The runtime to perform 5000 calculation steps for a 10,000 zone model of Mohr-Coulomb material is roughly 12 minutes on a 2.8 GHz Pentium IV microcomputer.† The number of calculation steps required to reach a solution state with the explicit-calculation scheme can vary, but a solution typically can be reached within 3000 to 5000 steps for models containing up to 10,000 elements, regardless of material type. (The explicit-solution scheme is explained in Section 1 in **Theory and Background**.) With the advancements in floating-point operation speed, and the ability to install additional RAM at low cost, it should be possible to solve increasingly larger three-dimensional problems with *FLAC3D*.

FLAC3D can be operated from either a command-driven mode or a graphics menu-driven mode. The default command-driven mode is very similar to that used by other Itasca software products. You will find that most of the commands are the same as, or three-dimensional extensions of, those in *FLAC*. A menu-driven, graphical user interface is also available in *FLAC3D* for performing plotting, printing and file access.

---

* Itasca Consulting Group, Inc. ***FLAC (Fast Lagrangian Analysis of Continua.)***, Version 5.0, 2005.

† See Section 5 for a comparison of *FLAC3D* runtimes on various computer systems.

With the graphics facilities* built into *FLAC3D*, high-resolution, color-rendered plots are generated quite rapidly. We have developed a graphics screen-plotting facility that allows you to instantly view the model during creation from either command-mode or graphics menu-mode. The model can be translated, rotated and magnified on the screen for better viewing. Color-rendered plots of surfaces showing vectors or contours can be made in 3D, and a two-dimensional plane can be located at any orientation and location in the model for the purpose of viewing vector or contour output on the plane. All output can be directed to a black-and-white or color hardcopy device, to the Windows clipboard, or to a file.

You will find that *FLAC3D* offers a facility for problem solving similar to the one in *FLAC*. A comparison of *FLAC3D* to other numerical methods, a description of general features and updates in *FLAC3D* Version 3.1, and a discussion of fields of application are provided in the following sections. If you wish to try *FLAC3D* right away, the program installation instructions and a simple tutorial are provided in Section 2.

* The graphics facilities in *FLAC3D* utilize the Windows GDI.

1.2 Comparison with Other Methods

How does *FLAC3D* compare to the more common method of using finite elements for numerical modeling? Both methods translate a set of differential equations into matrix equations for each element, relating forces at nodes to displacements at nodes. Although *FLAC3D*'s equations are derived by the finite difference method, the resulting element matrices for an elastic material are identical to those of the finite element method (for constant-strain tetrahedra). However, *FLAC3D* differs in the following respects:

1. The "mixed discretization" scheme (Marti and Cundall, 1982) is used for accurate modeling of plastic collapse loads and plastic flow. This scheme is believed to be physically more justifiable than the "reduced integration" scheme commonly used with finite elements.

2. The full dynamic equations of motion are used, even when modeling systems are essentially static. This enables *FLAC3D* to follow physically unstable processes without numerical distress. The approach to provide a time-static solution is discussed in the definition for "Static Solution" given in Section 2.3.

3. An "explicit" solution scheme is used (in contrast to the more usual implicit methods). Explicit schemes can follow arbitrary nonlinearity in stress/strain laws in almost the same computer time as linear laws, whereas implicit solutions can take significantly longer to solve nonlinear problems. Furthermore, it is not necessary to store any matrices, which means: (a) a large number of elements may be modeled with a modest memory requirement; and (b) a large-strain simulation is hardly more time-consuming than a small-strain run, because there is no stiffness matrix to be updated.

4. *FLAC3D* is robust in the sense that it can handle any constitutive model with no adjustment to the solution algorithm; many finite element codes need different solution techniques for different constitutive models.

These differences are mainly in *FLAC3D*'s favor, but there are two disadvantages:

1. Linear simulations run more slowly with *FLAC3D* than with equivalent finite element programs. *FLAC3D* is most effective when applied to nonlinear or large-strain problems, or to situations in which physical instability may occur.

2. The solution time with *FLAC3D* is determined by the ratio of the longest natural period to the shortest natural period in the system being modeled. This point is discussed in more detail in Section 1 in **Theory and Background**, but certain problems are very inefficient to model (e.g., beams, represented by solid elements rather than structural elements, or problems that contain large disparities in elastic moduli or element sizes).

1.3 General Features

1.3.1 Basic Features

FLAC3D offers a wide range of capabilities to solve complex problems in mechanics, and especially in geomechanics. Like *FLAC*, *FLAC3D* embodies special numerical representations for the mechanical response of geologic materials. The program has twelve basic built-in material models: the "null" model; three elasticity models (isotropic, transversely isotropic and orthotropic elasticity); and eight plasticity models (Drucker-Prager, Mohr-Coulomb, strain-hardening/softening, ubiquitous-joint, bilinear strain-hardening/softening ubiquitous-joint, double-yield, modified Cam-clay and Hoek-Brown). These models are described in detail in Section 2 in **Theory and Background**. Each zone in a *FLAC3D* grid may have a different material model or property, and a continuous gradient or statistical distribution of any property may be specified.

Additionally, an interface, or slip-plane, model is available to represent distinct interfaces between two or more portions of the grid. The interfaces are planes upon which slip and/or separation are allowed, thereby simulating the presence of faults, joints or frictional boundaries. The interface model is described in Section 3 in **Theory and Background**.

FLAC3D contains an automatic 3D grid generator in which grids are created by manipulating and connecting pre-defined shapes.* The generator permits the creation of intersecting internal regions (e.g., intersecting tunnels). The 3D grid is defined by a global x,y,z-coordinate system (rather than in a row-and-column fashion as in *FLAC*). This provides more flexibility in model creation and definition of parameters in a three-dimensional space. Grid generation procedures are described in Section 1 in the **Command Reference** under the **GENERATE** command.

Boundary conditions and initial conditions are specified in much the same way as in *FLAC*. Either velocity (and displacement) boundary conditions, or stress (and force) boundary conditions, may be specified at any boundary orientation. Initial stress conditions, including gravitational loading, may also be given, and a water table may be defined for effective stress calculations. All conditions may be specified with gradients. Boundary conditions are primarily assigned via the **APPLY** command, and initial conditions via the **INITIAL** command, as described in Section 1 in the **Command Reference**.

FLAC3D incorporates the facility to model groundwater flow and pore-pressure dissipation, and the full coupling between a deformable porous solid and a viscous fluid flowing within the pore space. (The coupled interaction is described further in Section 1.3.3.) The fluid is assumed to obey either the isotropic or anisotropic form of Darcy's law. Both the fluid and the grains within the porous solid are deformable. Non-steady flow is modeled, with steady flow treated as an asymptotic case. Fixed pore pressure and constant-flow boundary conditions may be used, and sources and sinks (wells) may be modeled. The flow model can also be run independent of the mechanical calculation, and both confined and unconfined flow can be simulated, with automatic calculation of the phreatic surface. The fluid-flow model is described in Section 1 in **Fluid-Mechanical Interaction**.

---

* An optional meshing preprocessor is also available – see Section 1.3.2.

Structures such as tunnel liners, piles, sheet piles, cables, rock bolts or geotextiles, that interact with the surrounding rock or soil, may be modeled with the structural element logic in *FLAC3D*. It is possible to either examine the stabilizing effects of supported excavations, or to study the effects of soil or rock instability on surface structures. The different types of structural elements are described in Section 1 in **Structural Elements**.

A factor of safety can be calculated automatically for any *FLAC3D* model composed of Mohr-Coulomb material. The calculation is based on a "strength reduction technique" that performs a series of simulations while changing the strength properties to determine the condition at which an unstable state exists. A factor of safety which corresponds to the point of instability is found, and the critical failure surface is located in the model. The factor-of-safety algorithm is described in Section 3.8.

FLAC3D also contains a powerful built-in programming language, *FISH*, that enables the user to define new variables and functions. *FISH* offers a unique capability to users who wish to tailor analyses to suit their specific needs. For example, *FISH* permits:

- user-prescribed property variations in the grid (e.g., nonlinear increase in modulus with depth);
- plotting and printing of user-defined variables (i.e., custom-designed plots);
- implementation of special grid generators;
- servo-control of numerical tests;
- specification of unusual boundary conditions; variations in time and space; and
- automation of parameter studies.

An introduction to *FISH* is given in Section 4. See Section 2 in the ***FISH* volume** for a detailed reference to the *FISH* language.

FLAC3D contains extensive graphics facilities for generating plots of virtually any problem variable. Three-dimensional graphics rendering is provided in high-resolution video modes. Plotting features include hidden surface plots, surface contour plots and vector plots. Plotted variables can be viewed in front of, behind, or on an arbitrary cross-section plane through, the model. This version of *FLAC3D* has been compiled as a native Windows executable using the WIN32 API to support execution under Windows 98 and later operating systems. The program has the look and feel of a typical Windows program; however, most modeling operations are performed in the command-driven mode, while the graphical user interface supports file-handling, model and response visualization (plotting), and printing (using standard Windows file-handling and printing facilities). Plotting operations are described in Section 1 in the **Command Reference** under the **PLOT** command.

1.3.2 Optional Features

Four optional features (for dynamic analysis, thermal analysis, modeling creep-material behavior, and writing user-defined constitutive models) are available as separate modules that can be included in *FLAC3D* at an additional cost per module. Also, a fifth optional feature, a hexahedral-meshing preprocessor (*3DShop*), is available as a separate program, at an additional cost.*

Dynamic analysis can be performed with *FLAC3D*, using the optional dynamic-calculation module. User-specified acceleration, velocity or stress waves can be input directly to the model, as either an exterior boundary condition or an interior excitation to the model. *FLAC3D* contains absorbing and free-field boundary conditions to simulate the effect of an infinite elastic medium surrounding the model. The dynamic calculation can be coupled to the groundwater flow model; the level of coupling, including dynamic pore-pressure generation (liquefaction), is discussed in Section 1.3.3. The dynamic analysis capability is described in Section 3 in **Optional Features**.

There is a thermal analysis option available as a special module in *FLAC3D*. This model simulates the transient flux of heat in materials, and the subsequent development of thermally induced stresses. The thermal model can be run independently, or coupled to the mechanical-stress calculation or pore-pressure calculation, either static or dynamic. (The coupling interactions are described in Section 1.3.3.) The thermal analysis capability is described in Section 1 in **Optional Features**.

There are eight optional material models available that simulate time-dependent (creep) material behavior (All creep models are described in Section 2 in **Optional Features**.):

(1) the classical viscoelastic (Maxwell) model;

(2) a Burger's substance viscoelastic model;

(3) a two-component power law;

(4) a reference creep formulation (the WIPP model) implemented for nuclear waste isolation studies;

(5) a Burger-creep viscoplastic model combining the Burger's model with the Mohr-Coulomb model;

(6) a power-law viscoplastic model combining the two-component power law and the Mohr-Coulomb model;

(7) a WIPP-creep viscoplastic model combining the reference creep formulation with the Drucker-Prager plasticity model; and

(8) a "crushed-salt" model that simulates both volumetric and deviatoric creep compaction.

---

* The hexahedral-meshing preprocessor *3DShop*, enables the creation of complex meshes for *FLAC3D*. *3DShop* can substantially reduce model creation time. See Section 1 in the **Hexahedral-Meshing Preprocessor — *3DShop* volume** for more information and a tutorial on *3DShop*.

With this optional feature, user-defined constitutive models can be written in C++ and compiled as DLL (dynamic link library) files that can be loaded whenever needed. Microsoft Visual C++ Version 8.0 (Microsoft Visual Studio 2005) is used to compile the DLL files. The procedure to write new constitutive models and create DLLs is described in Section 4 in **Optional Features**.

1.3.3 Modeling Physical Processes and Interactions

The default calculation mode in *FLAC3D* is for static mechanical analysis. Alternatively, a groundwater flow analysis or a heat-transfer analysis can be performed, independent of the mechanical calculation. Both the groundwater flow and thermal models may be coupled to the mechanical stress model and to each other. Because the full equations of motion are used in *FLAC3D*, the coupling mechanisms operate in dynamic analyses as well as static analyses.

The coupling mechanisms are divided into three types of interaction: mechanical and groundwater flow; mechanical and thermal; and thermal and groundwater flow. The level of interaction modeled in *FLAC3D* for each type is described below.

Mechanical-Groundwater Flow Coupling — Several types of fluid/solid interaction can be specified in *FLAC3D*. One type of interaction is consolidation, in which the slow dissipation of pore pressure causes displacements to occur in the solid (e.g., soil). Two mechanical effects are at work in this case: (1) the fluid in a zone reacts to mechanical volume changes by a change in the pore pressure; and (2) the pore-pressure change causes changes in the effective stress that affect the response of the solid (e.g., a reduction in effective stress may induce plastic yield). Coupling between fluid and solid due to deformable grains can also be specified.

FLAC3D can calculate pore-pressure effects, with or without pore-pressure dissipation, simply by setting the flow calculation on or off. Also, dynamic pore-pressure generation (e.g., related to liquefaction) can be modeled by accounting for irreversible volume strain in the constitutive model. This is done with two different built-in constitutive models: the “Finn” model, and the “Byrne” model. Both models are provided with the dynamic option.

By default, porosity and permeability are assumed constant. However, these properties can be made a function of volumetric strain via a *FISH* function. As a consequence, two-way coupling of mechanical stress and groundwater flow can be modeled with *FLAC3D*.

Other types of interaction, such as capillary, electrical or chemical forces between particles of a partially saturated material, are not modeled directly by *FLAC3D*. But some of the effects may be included by providing suitable *FISH* functions. Similarly, a *FISH* function may be used to vary the local fluid modulus as a function of other quantities such as pressure or time.

Thermal-Mechanical Coupling — The thermal-mechanical coupling in *FLAC3D* is one-way: temperature change may induce a mechanical stress change as a function of the thermal-expansion coefficient. Mechanical changes in the body, however, do not result in temperature change or changes to thermal properties. Additionally, mechanical properties can be made a function of temperature change, since *FISH* permits access to both temperatures and properties.

Thermal-Groundwater Flow Coupling — The thermal calculation may be coupled to the groundwater flow calculation by making pore pressures a function of temperature change. Volumetric strain can arise from thermal expansion of both the fluid and the grains within a saturated matrix. Pore pressure change results from this volumetric strain, as well as from mechanical volumetric strain. Groundwater flow can also influence heat transfer; an advection model that takes the transport of heat by convection into account is provided. The advection model can also simulate temperature-dependent fluid density and thermal advection in the fluid.

As with mechanical properties, groundwater properties can be made a function of temperature change by accessing temperature and property values via *FISH*.

1.4 Summary of Updates from Version 3.0

FLAC3D 3.1 contains several improvements; the new features are summarized in the following sections. Existing data files created for Versions 3.0 and 2.1 should still operate as before. *FLAC3D* 3.1 will not be able to restore files saved by versions earlier than *FLAC3D* 2.1.

1.4.1 Parallel Processing on Multiprocessor Computers

Mechanical calculations of the main grid are now multithreaded and take advantage of multiple processors (e.g., dual processors or a dual core processor). On a two dual-core processor system, *FLAC3D* would split the mechanical computations among four cores. Parallel processing is a standard feature of *FLAC3D* 3.1, and a speed increase of approximately 1.8 times has been noted on two processor systems. Parallel processing also seamlessly integrates with user-defined models (UDMs). The mechanical calculations are automatically multithreaded when running *FLAC3D* 3.1 on a multiprocessor computer. The number of processors used for the multithreaded calculations can also be specified manually by issuing the **SET processors *n*** command, in which ***n*** is the number of processors to be used.

1.4.2 64-Bit Version

In addition to the 32-bit version of *FLAC3D* 3.1, a 64-bit version is available (at no additional cost). *FLAC3D* 32-bit is capable of creating models up to 2 GB in size. *FLAC3D* 64-bit will allow a virtually unlimited model size (17 billion GB of addressable memory). *FLAC3D* 64-bit does not offer a computational speed increase over the 32-bit version, but does allow extremely large models to be created. *FLAC3D* 64-bit has features identical to those in the 32-bit version, and save files created by either version are compatible. The 64-bit version will only operate on a 64-bit processor computer running the Windows XP X64 operating system.

1.4.3 Embedded Liner

The **SEL liner** implementation in *FLAC3D* only provides for interaction with the grid on one side of the liner. The new embedded liner logic (**SEL liner embedded**) extends the single-sided liner interaction to two sides. Shear-directed frictional interaction occurs independently on both sides of the embedded liner, and compressive and tensile forces are calculated separately on both sides in the normal direction. The embedded liner supports the following independent properties on each side: normal coupling-spring tensile strength and stiffness, shear coupling-spring cohesion, residual cohesion, friction angle and stiffness.

An embedded liner allows more accurate modeling of problems such as retaining walls, where interaction is required between the main grid and both sides of the retaining wall, with different properties on each side of the wall. See Section 1.9 in **Structural Elements** for additional information and an example application of the embedded liner.

1.4.4 Two-Dimensional Grid Extrusion Tool

A special grid-generation tool is available in Version 3.1 to create a three-dimensional *FLAC3D* mesh by extruding a two-dimensional *FLAC* grid. The grid-generation tool is a menu-driven graphical interface. A two-dimensional grid can be created directly within the tool, or a *FLAC3D* Version 5.0 data file can be loaded into the tool to create the extruded *FLAC3D* mesh. Two types of grid extrusions are available: a linear extrusion orthogonal to the two-dimensional grid plane, and an extrusion that revolves about an axis of revolution.

The powerful graphical user interface available with *FLAC* 5.0 (the *GIIC*) can be used to construct a complicated 2D cross-section (e.g., a tunnel with excavation sequence geometry). This 2D tunnel can then be extruded into a 3D model for use in *FLAC3D* 3.1. The *FLAC* 5.0 extrusion *GIIC* is directly accessible from a *FLAC3D* 3.1 menu item (FILE/FLAC EXTRUDE) or a command (**FLACEXTRUDE**). *FLAC* 5.0 needs to be installed, but a *FLAC* 5.0 license is not necessary to access this feature. See Section 3.2.4 for a description and example applications of the grid-extrusion tool.

1.4.5 Nodal Mixed Discretization

A Nodal Mixed Discretization (NMD) technique for use with linear tetrahedra has been implemented in *FLAC3D* 3.1. NMD overcomes the over-stiff behavior observed by these zones during plastic flow, due to the volumetric constraint introduced by plasticity. In this technique, the zone's volumetric behavior is averaged over the zones sharing its gridpoints. The effect of applying the NMD scheme is to increase the number of degrees of freedom per zone, thus accommodating the additional constraint imposed on each zone by, for example, the classical incompressibility condition for frictionless material. The advantage of the technique, compared to the standard mixed discretization scheme currently implemented in *FLAC3D*, is that it does not require a discretization of the domain into hexahedral zones. The logic thus allows for the use of tetrahedral mesh generation capabilities existing today. The NMD technique is described in detail in Section 1.2.2 in **Theory and Background**. The technique is invoked by specifying the **SET nmd on** command. (NMD is experimental at this stage.)

1.4.6 Built-in Help

In addition to the complete set of PDF manuals that is provided with *FLAC3D* 3.1, the **Command Reference**, **FISH in FLAC3D** and **Example Applications** volumes are available as built-in, searchable help through the *FLAC3D* 3.1 help menu or the **HELP** command.

1.4.7 New Features in FISH

The following new *FISH* variables have been added to *FLAC3D* 3.1 (see the ***FISH* in *FLAC3D*** volume for more details):

z_numoverlays	returns number of overlays (0, 1, or 2) in a zone
z_numtets	returns the number of tetrahedra in a specified overlay

z_gettetstress	gets the stress components from a specific tetrahedra in an overlay
z_puttetstress	puts stress components into a specific tetrahedra in an overlay
z_tetgps	gets the gridpoints associated with a specific tetrahedra in an overlay
z_nsmalltetvol	returns the volume of the smallest tetrahedra in an overlay
z_geomtest	returns 0 if zone has bad geometry, 1 if good
z_islive	returns 1 if the zone contains any "live" mechanical, fluid or thermal model
gp_near_live	returns a "live" gridpoint nearest to an ***x,y,z*** location
zone_near_live	returns a "live" zone nearest to an ***x,y,z*** location

The following *FISH* property functions have been added to support the embedded liner:

sl_csncut2	side 2 coupling spring tensile strength
sl_csnk2	side 2 normal coupling spring stiffness
sl_csscoh2	side 2 shear coupling spring cohesion
sl_csscohres2	side 2 shear coupling spring residual cohesion
sl_csscoh2	side 2 shear coupling spring friction angle
sl_cssk2	side 2 shear coupling spring stiffness
sl_embedded	returns 1 if the liner is embedded, 0 if not
nd_link2	returns the side2 link associated with an embedded liner node
lk_side	returns 1 if the link is a side1 link, returns 2 if it is a side2 link

1.4.8 New Commands

The following new commands have been added to *FLAC3D* 3.1 (see the **Command Reference** volume for more details):

SET **visible** keyword

Prior to *FLAC3D* 3.1, it was awkward to contour zone or gridpoint-related quantities when the model contained a null mechanical model, and a fluid or thermal-related quantity was being contoured (null mechanical zones were never plotted). With a keyword of **mechanical**, **fluid** or **thermal**, this command tells *FLAC3D* which zones to consider as visible when plotting.

SEL **join**

links two separate structural elements together. For example, a cable can be connected to a liner with this command.

SEL **refine**

subdivides existing segments of a 1D structural element (cable, beam or pile) into more segments.

SET **processor**

On a multiple processor system, this command will limit the number of processors used by *FLAC3D* 3.1 when performing mechanical calculations on the main grid.

FLACEXTRUDE

calls the *FLAC* 5.0 grid extrusion tool.

SET **nmd on/off**

For grids containing tetrahedral zones, the nodal mixed discretization technique can be enabled or disabled during the mechanical computations.

1.4.9 Revised Example Applications

Several existing examples were modified to use the NMD feature. In the **Verification Problems** volume, the following problems have been extended to use NMD: Section 1, Section 3, and Section 5.

Also, a user-defined *FISH* function for relaxing stresses in excavations is provided (see "ZONK3D.FIS" in Section 3.3.1.2).

1.5 Fields of Application

FLAC3D was developed primarily for geotechnical engineering applications. Section 6 contains a bibliography of publications on the application of *FLAC3D* to geotechnical problems in the fields of mining, underground engineering, rock mechanics and research.

Some possible applications of *FLAC3D* are noted below. Because *FLAC3D* now has essentially the same capabilities of *FLAC*, many of the *FLAC* applications can now be extended into three dimensions with *FLAC3D*:

- mechanical loading capacity and deformations — in slope stability and foundation design;
- evolution of progressive failure and collapse — in hard rock mine and tunnel design;
- factor-of-safety calculation — in stability analyses for earth structures, embankments and slopes;
- evaluation of the influence of fault structures — in mine design;
- restraint provided by cable support on geologic materials — in rock bolting, tiebacks and soil nailing;
- fully and partially saturated fluid flow, and pore-pressure build-up and dissipation for undrained and drained loading — in groundwater flow and consolidation studies of earth-retaining structures;
- time-dependent creep behavior of viscous materials — in salt and potash mine design;
- dynamic loading on slip-prone geologic structures — in earthquake engineering and mine rockburst studies;
- dynamic effects of explosive loading and vibrations — in tunnel driving or in mining operations;
- seismic excitation of structures — in earth dam design;
- deformation and mechanical instability resulting from thermal-induced loads — in performance assessment of underground repositories of high-level radioactive waste; and
- analysis of highly deformable materials — in bulk flow of materials in bins and mine caving.

1.6 Guide to the *FLAC3D* Manual

The *FLAC3D* Version 3.1 manual consists of ten documents. This document, the **User's Guide**, is the main guide to using *FLAC3D* and contains descriptions of the features and capabilities of the program, along with recommendations on the best use of *FLAC3D* for problem solving. The remaining documents cover various aspects of *FLAC3D*, including theoretical background information, verification testing and example applications. The complete manual is available in electronic format on the *FLAC3D* CD-ROM (viewed with Acrobat Reader*), as well as in paper format. Specific topics or keywords can be found across all volumes by implementing the search facility available in Acrobat.

The organization of the ten documents, and brief summaries of the contents of each section, follows. Please note that if you are viewing the manual in the Acrobat Reader, double-clicking on a section number given below will immediately open that section for viewing.

User's Guide

Section 1 Introduction

This section introduces you to *FLAC3D* and its capabilities and features. An overview of the new features in the latest version of *FLAC3D* is also provided.

Section 2 Getting Started

If you are just beginning to use *FLAC3D*, or use it only occasionally, we recommend that you read Section 2. This section provides instructions on installation and operation of the program, as well as recommended procedures for running *FLAC3D* analyses.

Section 3 Problem Solving

Section 3 is a guide to practical problem solving. Turn to this section once you are familiar with the program operation. Each step in a *FLAC3D* analysis is discussed in detail, and advice is given on the most effective procedures to follow when creating, solving and interpreting a *FLAC3D* model simulation.

Section 4 *FISH* Beginner's Guide

Section 4 provides the new user with an introduction to the *FISH* programming language in *FLAC3D*. This includes a tutorial on the use of the *FISH* language. *FISH* is described in detail in Section 2 in the ***FISH* volume**.

---

* "Acrobat(R) Reader copyright (C) 1987-2006, Adobe Systems Incorporated. All rights reserved. Adobe and Acrobat are trademarks of Adobe Systems Incorporated."

Section 5 Miscellaneous

Various information is contained in this section, including the *FLAC3D* runtime benchmark and procedures for reporting errors and requesting technical support. Descriptions of utility files to assist with *FLAC3D* operation are also given.

Section 6 Bibliography

This section contains a bibliography of published papers describing some uses of *FLAC3D*.

Command Reference

Section 1 Command Reference

All the commands that can be entered in the command-driven mode in *FLAC3D* are described in Section 1 in the **Command Reference**.

FISH in *FLAC3D*

Section 1 *FISH* Beginner's Guide

Section 1 in the ***FISH* volume** provides the new user with an introduction to the *FISH* programming language in *FLAC3D*. This includes a tutorial on the use of the *FISH* language.

Section 2 *FISH* Reference

Section 2 in the ***FISH* volume** contains a detailed reference to the *FISH* language. All *FISH* statements, variables and functions are explained and examples given.

Section 3 Library of *FISH* Functions

A library of common and general purpose *FISH* functions is given in Section 3 in the ***FISH* volume**. These functions can assist with various aspects of *FLAC3D* model generation and solution.

Theory and Background

Section 1 Theoretical Background

The theoretical formulation for *FLAC3D* is described in detail in Section 1 in **Theory and Background**. This includes both the description of the mathematical model that describes the mechanics of a system and the numerical implementation.

Section 2 Constitutive Models: Theory and Implementation

The theoretical formulation and implementation of the various built-in constitutive models are described in Section 2 in **Theory and Background**.

Section 3 Interfaces

The interface logic is described and example applications are given in Section 3 in **Theory and Background**. A discussion on interface properties is also provided.

Fluid-Mechanical Interaction

Section 1 Fluid-Mechanical Interaction

The formulation for the fluid-flow model is described, and the various ways to model fluid flow, both with and without solid interaction, are illustrated in Section 1 in **Fluid-Mechanical Interaction**.

Structural Elements

Section 1 Structural Elements

Section 1 in **Structural Elements** describes the various structural element models available in *FLAC3D*. These include beams, cables, piles, shells, liners and geogrids.

Optional Features

Section 1 Thermal Option

Section 1 in **Optional Features** describes the thermal model option, and presents several verification problems that illustrate its application both with and without interaction with mechanical stress and pore pressure.

Section 2 Creep Material Models

The different creep material models available as an option in *FLAC3D* are described, and verification and example problems are provided in Section 2 in **Optional Features**.

Section 3 Dynamic Analysis

The dynamic analysis option is described, and considerations for running a dynamic model are provided in Section 3 in **Optional Features**. Several verification examples are also included in this section.

Section 4 Writing New Constitutive Models

Users can write their own constitutive models for incorporation into *FLAC3D*. The models are written in C++, and compiled as a DLL file (dynamic link library) that can be loaded whenever it is needed. The procedure to create new models is described in Section 4 in **Optional Features**.

Hexahedral-Meshing Preprocessor — *3DShop*

Section 1 *3DShop*

3DShop is a hexahedral-meshing preprocessor that enables the creation of complex meshes for *FLAC3D*. *3DShop* uncouples the model building from the meshing process. The model is built via a menu-driven graphical interface, and then meshed using a fully automatic all-hexahedral mesh generator. See Section 1 in the **Hexahedral-Meshing Preprocessor — *3DShop* volume** for details.

Verification Problems

This volume contains a collection of *FLAC3D* verification problems. These are tests in which a *FLAC3D* solution is compared directly to an analytical (i.e., closed-form) solution. See Table 1 in the **Verifications volume** for a list of the verification problems.

Example Applications

This volume contains example applications of *FLAC3D* that demonstrate the various classes of problems to which *FLAC3D* may be applied. See Table 1 in the **Examples volume** for a list of the example applications.

1.7 Itasca Consulting Group, Inc.

Itasca Consulting Group, Inc. is more than a developer and distributor of engineering software. Itasca is a consulting and research firm comprised of a specialized team of civil, geotechnical and mining engineers with an established record in solving problems in the areas of:

Civil Engineering

Mining Engineering and Energy Resource Recovery

Nuclear Waste Isolation and Underground Space

Defense Research

Software Engineering

Groundwater Analysis and Dewatering

Itasca was established in 1981 to provide advanced rock mechanics services to the mining industry. Today, Itasca is a multidisciplinary geotechnical firm with 60 professionals in offices worldwide. The corporate headquarters for Itasca is located in Minneapolis, Minnesota. Worldwide offices of Itasca are operated as subsidiaries of HCItasca, Inc.: Hydrologic Consultants, Inc. (Denver, Colorado); Itasca Geomekanik AB (Stockholm, Sweden); Itasca Consultants S.A. (Ecully, France); Itasca Consultants GmbH (Gelsenkirchen, Germany); Itasca Consultores S.L. (Llanera, Spain); Itasca S.A. (Santiago, Chile); Itasca Africa (Johannesburg, South Africa); Itasca Consultants Canada Inc. (Sudbury, Canada); and Itasca Consulting China, Ltd. (Wuhan, China).

Itasca's staff members are internationally recognized for their accomplishments in geological, mining and civil engineering projects. Itasca staff consists of geological, mining, hydrological and civil engineers who provide a range of comprehensive services such as (1) computational analysis in support of geo-engineering designs, (2) design and performance of field experiments and demonstrations, (3) laboratory characterization of rock properties, (4) data acquisition, analysis, and system identification, (5) groundwater modeling, and (6) short courses and instruction in the geomechanics application of computational methods. If you should need assistance in any of these areas, we would be glad to offer our services.

Itasca Consulting Group is a subsidiary of HCItasca, Inc. HCItasca was formed in 1999 with the merger of Hydrologic Consultants, Inc. (HCI) of Denver, Colorado with Itasca Consulting Group, Inc. of Minneapolis, Minnesota. HCI adds advanced groundwater modeling and dewatering expertise to Itasca.

1.8 User Support

We believe that the support Itasca provides to code users is a major reason for the popularity of our software. We encourage you to contact us when you have a modeling question. We provide a timely response via telephone, electronic mail or fax. General assistance in the installation of *FLAC3D* on your computer, plus answers to questions concerning capabilities of the various features of the code, are provided free of charge. Technical assistance for specific user-defined problems can be purchased on an as-needed basis.

If you have a question, or desire technical support, please contact us at:

Itasca Consulting Group, Inc.
Mill Place
111 Third Avenue South, Suite 450
Minneapolis, Minnesota 55401 USA

Phone: (+1) 612-371-4711
Fax: (+1) 612·371·4717
Email: software@itascacg.com
Web: www.itascacg.com

We also have a worldwide network of code agents who provide local technical support. Details may be obtained from Itasca.

2 GETTING STARTED

This section provides the first-time user with an introduction to *FLAC3D*. *Getting Started* contains instructions for program installation and start-up on your computer. It also outlines the recommended procedure for applying *FLAC3D* to problems in geo-engineering and includes simple examples that demonstrate each step of this procedure.

If you are familiar with the program but only use it occasionally, you may find this section (in particular, Section 2.7) helpful in refreshing your memory on the mechanics of running *FLAC3D*. More complete information on problem solving is provided in Section 3.3.

FLAC3D can be operated in either a *command-driven* or graphical, *menu-driven* mode.* For most of the examples in this manual, input is entered and results are viewed using the command-driven mode. We believe this is the clearest way for you to understand the operating procedures for *FLAC3D*. As explained previously in Section 1.1, the command-driven structure allows *FLAC3D* to be a very versatile tool for use in engineering analysis. However, this structure can present difficulties for new or occasional users. Command lines must be entered as input to *FLAC3D*, either interactively via the keyboard or from a remote data file, in order for the code to operate. There are over 40 main commands and over 400 command modifiers (called *keywords*) that are recognized by *FLAC3D*.

Getting Started contains the following information.

1. A step-by-step procedure to install and start up *FLAC3D* on your computer is given in Section 2.1. This includes the system requirements for operating *FLAC3D*, a description of the components of the *FLAC3D* program and related files, the memory allocation, utility software and graphics devices, start-up and operation procedures, program initialization, identification of version number, and installation tests.

2. This is followed in Section 2.2 with a simple tutorial to help you become familiar with common input commands.

3. There are a few things you will need to know before creating and running your own *FLAC3D* model — i.e., you need to know the *FLAC3D* terminology. The nomenclature used for this program is described in Section 2.3. The definition of a *FLAC3D* finite difference grid is given in Section 2.4. You should also know the syntax for the *FLAC3D* input language; an overview is provided in Section 2.5.

4. A special feature of *FLAC3D* — i.e., the capability to create, name and use objects in a model — can greatly facilitate problem solving; this is introduced in Section 2.6.

---

* The graphical user interface is only partially implemented at this time. The primary use of the current version is in accessing plotting functions and handling files. The last section of *Getting Started* (Section 2.12) is an introduction to the graphical user interface in *FLAC3D*, and provides an example that is run in the menu-driven mode.

5. The mechanics of running a *FLAC3D* model are described in separate steps; in Section 2.7, each step is discussed separately and simple examples are provided.
6. The sign conventions, systems of units and precision limits used in the program appear in Sections 2.8, 2.9 and 2.10, respectively.
7. The different types of files used and created by *FLAC3D* are described in Section 2.11.
8. An introduction to the graphical user interface is provided in Section 2.12.

2.1 Installation and Start-up Procedures

2.1.1 System Requirements

To install and operate *FLAC3D*, your computer must meet the following minimum requirements.

Processor — A processor with a minimum clock speed of 2 GHz is recommended. The speed of calculation for a *FLAC3D* model is directly related to the processor's speed. Therefore, the selection of a high-speed processor is a key factor for improving computation efficiency.

Hard Drive — At least 15 MB of hard disk space must be available to install *FLAC3D*. If the online *FLAC3D* manual is copied to the hard disk, an additional 21 MB are required. (Note that, by default, the manual will be installed on the hard drive.) Also, a minimum of 100 MB disk space should be available for model save files.

RAM — The minimum amount of RAM required to load *FLAC3D* is 3 MB. The memory allocated for a *FLAC3D* model is adjusted dynamically to take up the required RAM for a model at the time the model is created (see Table 2.1).

Generally, the combined RAM needed by *FLAC3D* and its model storage should leave 0.5 to 1 GB available to Windows; otherwise, Windows starts swapping into virtual RAM (on disk) — this swapping causes a dramatic performance loss in *FLAC3D*. The more applications there are running simultaneously, the smaller the *FLAC3D* model should be.

Finally, it should be noted that the Windows 32-bit operating systems impose an upper limit of 2 GB RAM on *FLAC3D* models. *FLAC3D* (64-bit) models can access a much larger amount of memory (theoretically 2^{64} bytes are accessible).

Display — For best performance, a screen resolution of 1024 × 768 pixels and a 16-bit color palette is recommended.

Operating System — *FLAC3D* is available as a 32-bit or 64-bit native Windows application. *FLAC3D* running on Microsoft Windows 2000, Windows XP and XP x64 Edition are currently supported by Itasca.

Output Device — By default, plots from *FLAC3D* are sent directly to the Windows native printer. Plots can also be directed to the Windows clipboard, or to files encoded in PostScript, Enhanced Metafile format and bitmap formats (PCX or BMP). See the **SET plot command** for the selections of output format.

Operation on PC Networks — A network version of *FLAC3D* is available. The network key allows a single hardware dongle to be placed at a central location. Individual users can then run *FLAC3D* from any computer on the network. Network keys require a special licensing arrangement and installation. Contact Itasca for details.

2.1.2 Installation of FLAC3D

FLAC3D is installed from a CD-ROM and is designed specifically to operate on Microsoft Windows systems (Windows 2000, Windows XP and XP x64 Edition are currently supported).

A default installation of *FLAC3D* from the CD-ROM will install the program, its example files, and the complete *FLAC3D* manual. The Adobe Reader is necessary for viewing the manual; this program is available to download for free from the Adobe Corporation (http://www.adobe.com).

To begin installation, insert the CD-ROM into the appropriate drive. If the autorun feature for the CD drive is enabled, a menu providing options for using the CD will appear automatically. If this menu does not appear, type "`[cd drive]:\start.exe`" at the command line (START –> RUN in Windows) to access the CD-ROM menu. The option to install *FLAC3D* may be selected from this menu.

The installation program will guide you through installation. When the installation is finished, a file named "INSTNOTE.PDF" will be found in the program sub-folder ("FLAC3D310") that resides in the main installation folder. (This is the folder that is specified during the installation process as the location to which files will be copied; by default, this is "c:\Program Files\Itasca.") The "INSTNOTE.PDF" file provides a listing of the directory structure that is created on installation, and a description of the actions that have been performed as part of the installation. This information may be used, in the unlikely event it is necessary or desirable, to either manually install or manually uninstall *FLAC3D*. The recommended method for uninstalling *FLAC3D* is to use the Windows "Add/Remove Programs" applet (START –> SETTINGS –> CONTROL PANEL –> ADD/REMOVE PROGRAMS). Please note that references made to files in the *FLAC3D* manual presume the default directory structure described in "INSTNOTE.PDF"; all data files described in the manual are contained in these folders.

The first time you load *FLAC3D* you will be asked to enter a customer title. This two-line title will appear on graphics screen plots and hardcopy plots. The title can be changed by using the **SET cust1** and **SET cust2** commands. The customer title is stored with the configuration settings in your computer's system registry.

After installing the software, connect the *FLAC3D* hardware key to the LPT1 or USB port on the computer before using the code.

2.1.3 Components of FLAC3D

The executable file for *FLAC3D* is "F3310.EXE," which is stored, by default, in the directory "\ITASCA\FLAC3D310." *FLAC3D* is compiled with the Microsoft Visual C++ (VC++) Version 8.0 compiler. In addition to the executable code, two sets of dynamic linked libraries (DLLs) are provided. One set of DLLs is used to access the various graphics formats in *FLAC3D*. The other set corresponds to the built-in constitutive models provided with *FLAC3D*. All of these DLLs are located in the "\ITASCA\FLAC3D310" directory.

2.1.4 Utility Software and Graphics Devices

Several types of utility software and graphics devices that can be of great help while operating *FLAC3D* are available.

Editors — A text editor is used to create *FLAC3D* input data files. Any text editor that produces standard ASCII text files may be used. Care must be taken if more "advanced" word-processing software (e.g., WordPerfect, Word) is used: this software typically encodes format descriptions into the standard output format; these descriptions are not recognized by *FLAC3D* and will cause an error. *FLAC3D* input files must be in standard ASCII format.

Graphic Output — FLAC3D supports several different types of graphics devices. By default, plots generated with the **PLOT hardcopy** command (or via the File Print View menu item from the main *FLAC3D* window) will be directed to the default Windows printer. (Note that the default printer is changed outside *FLAC3D* using the Printers folder in the My Computer object.) The Windows printer output is also selected with the **SET plot windows** command.

The command **PLOT clipboard** directs the current plot to the Windows clipboard (no file is generated). The image is in Enhanced Metafile format and subsequently may be pasted into another Windows application that is compatible with that format.

The **SET plot metafile** command directs output to an Enhanced Metafile format file on disc, where it can be saved for reference or later embedded in a Windows document. The **SET output** command should be used to set the output filename to one with an ".EMF" extension.

Either a black-and-white or color PostScript printer may be specified with the **SET plot postscript** command. The PostScript output may be written to a file for subsequent modification by a graphics program that will read the PostScript format.

PCX and BMP graphics formats can be accessed via the keywords **pcx**, **bitmap** or **bmp** with the **SET plot** command. Image resolution for these bitmap formats may be set using the **SET plot** <**output type**> **size** command. Also, the **SET plot avi** (AVI), **SET plot dcx** (DCX) and **MOVIE** commands enable one to make movies from graphic output.

Note that the different graphic output types can also be selected from the File Output Type menu item in the main *FLAC3D* window.

2.1.5 Start-up

A default installation will create an Itasca group under Programs on the user's Start menu in Windows. The Itasca group contains the FLAC3D –> FLAC3D310 shortcut that may be used to start the code. Be sure that the *FLAC3D* hardware key is attached to the LPT1 or USB port on the computer before starting the code.

A *FLAC3D* window is created when *FLAC3D* is loaded. A command window is also created within the main window, and command input can then be entered directly on the command line following the `Flac3D>` prompt.

When loaded, *FLAC3D* allocates memory dynamically (i.e., memory usage increases as the model is constructed). As a rule-of-thumb, it is recommended that 4 to 6 MB RAM be available to Windows after a complete *FLAC3D* model is generated. Otherwise, Windows will start swapping into virtual RAM — this swapping can cause a dramatic performance-loss in *FLAC3D*. Also, if other applications are running simultaneously, less RAM will be available for *FLAC3D*.

After loading *FLAC3D*, type

```
print memory system
```

This command will output the amount of memory currently used by *FLAC3D* (this is the same amount of memory as reported by Windows Task Manager). This number will vary with the model size.

Table 2.1 summarizes the approximate amount of RAM used when creating a number of zones of Mohr-Coulomb material with *FLAC3D* (32-bit). RAM usage increases by approximately 15% for the same model with *FLAC3D* (64-bit). Save file sizes are identical with both 32- and 64-bit versions, and are interchangeable between versions. *FLAC3D* (32-bit) can access up to 2 GB of memory (a 32-bit Windows operating system restriction). *FLAC3D* (64-bit) is able to accesses a virtually unlimited amount of memory (2^{64} bytes of addressable memory). It is advisable to have enough RAM available to accommodate the entire *FLAC3D* model, and to have some available for the operating system to function. If this is not the case, then the calculation performance may suffer due to excessive disk swapping (page-faults) in the Windows virtual memory system.

Table 2.1 FLAC3D RAM usage

Number of Zones	RAM Used (MB)
20^3	30
30^3	82
40^3	182
50^3	340

FLAC3D may be run from the command line, and will support command-line arguments, which may follow the executable name. If such arguments are present, each argument is interpreted as either a save file or a data file. If the file is not a valid save file, then it is assumed to be a data file. For save files, a **RESTORE** command is executed automatically. For data files, a **CALL** command is executed automatically. Multiple arguments are called or restored in the order specified. Also, to enable easier use of batch-file processing of multiple data files, the keyword **quit** can be given on the command line, which will cause the code to execute a **STOP** command and exit completely.

2.1.6 Version Identification

The version number of *FLAC3D* follows a simple numbering system that identifies the level of updates in the program. There are three numerical identifiers in the version number — that is,

```
Version I.JK
```

where:

- `I` is an integer starting with 1 that identifies a major release of the code;
- `J` is an integer that is incremented whenever a modification is made that requires a major change to the code structure for a supplemental upgrade release of *FLAC3D*; and
- `K` is an integer that is incremented when minor modifications are officially released as an update to the current version.

Note that *FLAC3D* Version 3.1 will restore save files from Version 3.0 and Version 2.1, but not versions earlier than 2.1. This is a result of the change from the Watcom C/C++ compiler to the Microsoft Visual C++ compiler. Existing data files should run correctly.

In addition to the version number, *sub-version* numbers are also used to identify minor changes to *FLAC3D* that have been made since the official version was released. Users may obtain the latest sub-version of the current version of *FLAC3D* from Itasca's web site (www.hcitasca.com). However, *FLAC3D* with a sub-version number greater than that of the officially released version should be used with caution, because all features have not been tested.

The version number for *FLAC3D* appears in the title bar of the *FLAC3D* main window. By typing the command

```
print version
```

the complete version number, including the sub-version number, can be obtained.

2.1.7 Program Initialization

On start-up, *FLAC3D* will look for the file named "FLAC3D.INI" in the current folder and then, if not found, in the "c:\Program Files\Itasca" folder. The "FLAC3D.INI" file can contain any *FLAC3D* commands that preset attributes of the program that you may wish to apply every time *FLAC3D* is used.

If the file "FLAC3D.INI" does not exist, *FLAC3D* simply continues without error. Note that some commands in a "FLAC3D.INI" file may result in an error message if they are inappropriate for the initial stage of a run.

2.1.8 Running FLAC3D

FLAC3D can be run interactively or from an input data file in command-driven mode. If you wish to run the code interactively, just begin typing in commands in the command window. *FLAC3D* will execute each command as the <ENTER> key is pressed. If an error arises, an error message will be displayed on the screen.

As an alternative, an input data file may be created using a text editor (see Section 2.1.4). This file contains a set of commands just as they would be entered in the interactive mode. Although the data file may have any name, a common identifying extension (e.g., ".DAT") will help to distinguish it from other *FLAC3D* files (see Section 2.11).

The data file can be read into *FLAC3D* by typing the command

```
call  file.dat
```

on the command line in the command window, in which "FILE.DAT" is the user-assigned name for the data file. You will see the data entries scroll up the screen as *FLAC3D* reads each line.

If the called file is located in the same folder as that from which "FLAC3D.EXE" is currently running, then only the file name need be entered with the **CALL** command. Otherwise, the file may be called by specifying its complete path (e.g., c:\myfolder\file.dat). Alternatively, a file can be called from any directory by using the FILE CALL menu (see Section 2.12).

It is also possible to create a shortcut to *FLAC3D* from a different directory. In the Windows Explorer, navigate to "F3310.EXE" (by default, in "c:\Program Files\Itasca\FLAC3D310"). Right-click on "F3310.EXE" and drag the file to the location where the shortcut is to be created (e.g., the directory containing the *FLAC3D* data files). When you release the right mouse button, a context menu will appear. Select "Create Shortcut Here" and a shortcut will be created. Double-click on the shortcut to start *FLAC3D*.

In order for *FLAC3D* to search for files in the shortcut directory instead of the directory containing "F3310.EXE," right-click on the shortcut and select "Properties." Delete the contents in the "Start In" edit box. This will cause *FLAC3D* to search the local folder for data files rather than the folder in which the executable is installed.

2.1.9 Installation Tests

Three simple data files, "TEST1.DAT," "TEST2.DAT" and "TEST3.DAT," are included in the "\FLAC3D310" directory so that you can test whether *FLAC3D* is installed properly on your computer. These files test the calculation kernel, the graphics screen-plotting and the hardcopy plotting facilities for your computer. In order to run the third test, your computer must be connected to a Windows printer.*

---

* For users who have printers connected to the LPT1 port: the *FLAC3D* hardware key is transparent to other uses of the LPT1 port; your printer can be attached directly to the key.

To run these tests, load the file "TEST1.DAT" from the "\FLAC3D310" directory via the FILE CALL menu, or type

```
call test1.dat
```

at the Flac3D> prompt and press <ENTER>.

Several data entries should scroll up the screen, and a simple model will be executed for 100 calculation steps. Example 2.1 contains the results of a successful "TEST1.DAT" run.

Example 2.1 FLAC3D output from "TEST1.DAT"

```
Zone Principal Stresses ...
   id      Maximum    Intermediate     Minimum
 ------ ------------- ------------- -------------
      1 -4.92673e+005 -4.92673e+005 -8.62177e+005
```

Now, load the file "TEST2.DAT" from the "\FLAC3D310" directory, or enter the command

```
call test2.dat
```

A screen plot of this model should appear. The plot is a color-rendered contour plot of displacements. Press the <ENTER> key to return to the Flac3D> prompt.

If your computer is connected to a Windows printer, load the file "TEST3.DAT" from the "\FLAC3D310" directory, or type

```
call test3.dat
```

and the plot shown in Figure 2.1 should be sent to your printer, and the program should exit. If you do not have a printer connected, do not load "TEST3.DAT." Type

```
quit
```

to exit *FLAC3D*.

If you are not able to reproduce the results of any or all of these three tests, you should review the system requirements and installation steps in Section 2.1. If you are still having difficulty, we recommend that you contact Itasca and describe the problem you have encountered and the type of computer you are using (see Section 5.2 for error-reporting procedures).

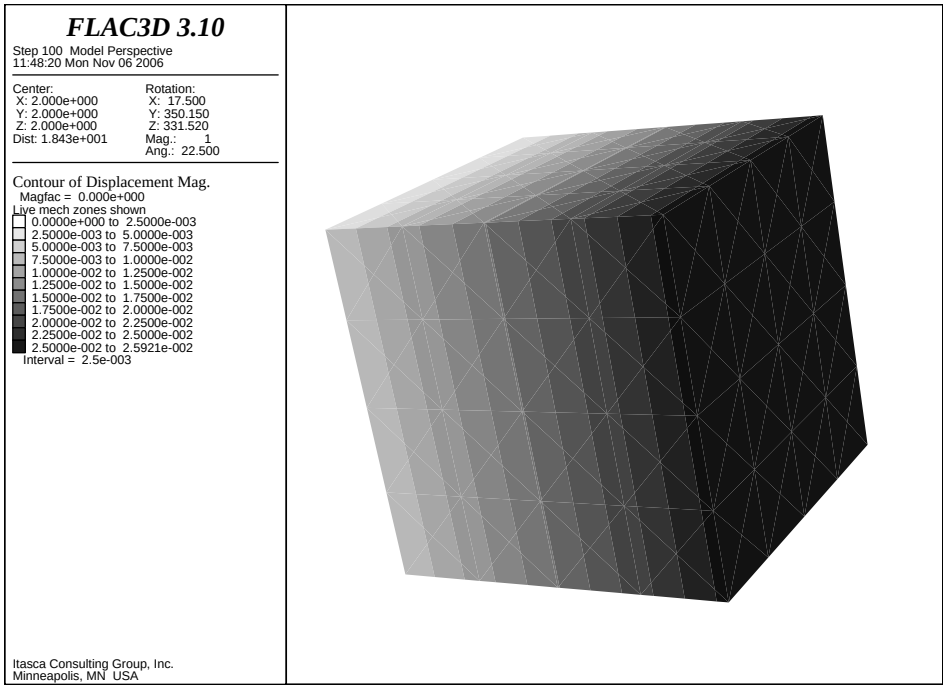

Figure 2.1 Windows plot from "TEST3.DAT"

2.2 A Simple Tutorial — Use of Common Commands

This section is provided for the new user who wishes to begin experimenting with *FLAC3D* right away. A simple example is presented to help you learn some of the basic aspects of solving problems with *FLAC3D*.

The example problem is a 2 m × 4 m trench excavated to a depth of 4 m in a soil mass. For this tutorial, we excavate the entire trench instantaneously and monitor the resulting movement of the material around the trench. For your convenience, the data file "TUT.DAT," included in the "\Tutorial\Beginner" directory, contains all the commands we are about to enter.

We run this problem interactively (i.e., by typing the commands from the keyboard, pressing <ENTER> at the end of each command line, and seeing the results directly). To begin, load *FLAC3D* by clicking the appropriate icon in the ITASCA group. Your computer will load the program and display the *FLAC3D* main window containing the command window with a command line beginning with the interactive prompt `Flac3D>`.

To set up the initial finite difference grid, use the **GENERATE** command:*

```
gen zone brick size 6 8 8
```

This command will create an initial mesh that is six zones in the x-direction, eight zones in the y-direction and eight zones in the z-direction. For our model, the z-axis is oriented in the vertical direction.

The model grid can be viewed by entering the plotting mode in *FLAC3D*. Type the command

```
plot
```

and the `Plot Base/0>` prompt will appear. As long as this prompt appears, any subsequent commands will be associated with the **PLOT** command. The plot view is identified as `Base/0`, which is the default view.

In order to create a view containing a color-rendered surface plot of the model, along with the model axes, type the commands shown in Example 2.2:

Example 2.2 Creating and using a plot view

```
create Trench
add surface yellow
add axes black
show
```

* See the command reference list in Section 1 in the **Command Reference** for further details. Note that command words can be abbreviated, and that words and values can be separated by any number of spaces and "=" signs (see Section 2.5).

This creates a plot view called `Trench`, and adds a surface plot item (in yellow) and an axes plot item (in black) to the view. The **show** keyword displays the current view (in a plot window with the view name `Trench` in the title bar); a view is automatically made current when it is created. A perspective view of the model, seen in elevation, will appear in the view window. This plot can be rotated in the *x*-, *y*- and *z*-directions by pressing the <X>, <Y> and <Z> keys on the keyboard. Use the <M> key to change the magnification, and the arrow keys to move the plot around. (To reverse the rotation and magnification, hold down the <SHIFT> key when pressing the appropriate key. Also, see Table 1.2 in the **Command Reference** for other keystrokes to manipulate the view of the model.) A plot similar to that shown in Figure 2.2 will appear on your screen. The orientation in the figure was achieved by reducing the magnification (<SHIFT-M> once) and rotating the plot about the *x*- (<X> twice) and *z*- (<Z> three times) axes.

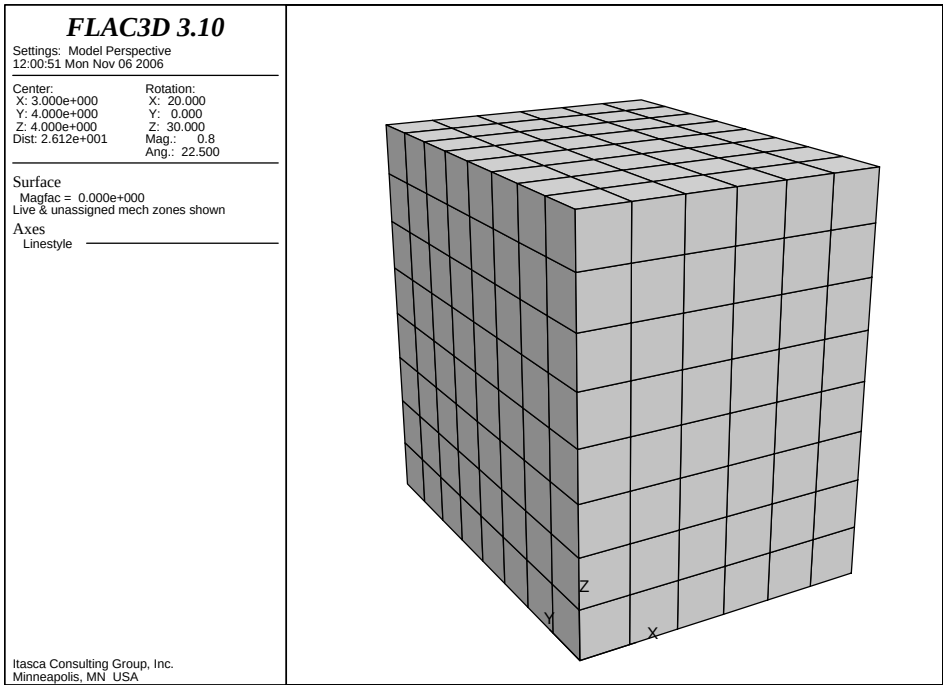

Figure 2.2 Brick-type mesh for trench example

Note that we can specify the magnification and orientation with **PLOT** commands directly. The caption of the plot shown in Figure 2.2 gives the data under the headings "Center:," "Rotation:," "Dist:" and "Mag:." So, after we interactively set up the view we want, we can transfer the data to a data file to facilitate the comparison of like views. Let's create another view, building on Example 2.2 — the new commands added in Example 2.3 are in **boldface** for clarity. (We are assuming that the `Plot Trench>` prompt in the command window is active; if not, move and click the mouse on the command window before typing the commands in Example 2.3.)

Example 2.3 Specifying view parameters

```
create Trench2
add surface yellow
add axes black
set rotation 20.0 0.0 30.0
set center 3 4 4
set dist 26.12
set magnification 0.8
show
```

Compare this view with that in Figure 2.2; they should be identical.

Now, we introduce some plotting features to enhance the output. The command

```
title 'Tutorial Examples'
```

was given at the start of the series of runs to produce the plots in this section. This title appears as a job title on all the plots. For individual plots, the command

```
plot set title text 'string'
```

will set the view title to *string*. For example, the command

```
plot set title text 'Mesh for trench example'
```

creates the title shown in Figure 2.2. These titles can be positioned at the top or bottom of the plot, or turned off completely. The **PLOT** command, described in Section 1.3 in the **Command Reference**, lists all of the options.

In order to make a hardcopy output of this plot, return to the `Plot Trench2>` prompt by moving and clicking the mouse on the command window, or by pressing the <ENTER> key. Then type

```
hard
```

By default, this will send the plot to the current Windows printer connected to the LPT1 port. The output type can be changed, if desired, as discussed in Section 2.1.4.

To close plot view `Trench2`, type

```
close
```

Now, only view `Trench` is displayed.

The mesh in Figure 2.2 is 6 m × 8 m × 8 m in size, with origin (x = 0, y = 0, z = 0) at the bottom-left corner. The dimensions, origin and mesh grading of the model can be changed with additional keywords specified after the **GENERATE** command. This will be explained later in this section.

Now give the zones a material model and properties. For this example, we use the Mohr-Coulomb elastic-plastic model. Go back to the `Flac3D>` prompt in the command window and type in

```
model mohr
```

This will specify the Mohr-Coulomb model. Every zone in the grid could conceivably have a different material model and property. However, if a range of zones is not specified after the **MODEL** command, *FLAC3D* assumes that all zones are to be Mohr-Coulomb material.

Each zone is automatically subdivided into tetrahedral "sub-zones." Two sets of five tetrahedra are overlaid in each zone ("double-overlay") in order to provide accurate solutions for plasticity analyses (see Section 1 in **Theory and Background** for an explanation of the numerical formulation for plasticity).

The amount of memory required to run this problem can be found by typing

```
print mem sav mem sys
```

This will give a listing of the memory statistics for the model at this state. Our problem requires approximately 0.8 MB to save the current state and approximately 13 MB to run this model.

The material properties are given next with the commands

```
prop bulk = 1e8 shear = 0.3e8 fric = 35
prop coh = 1e10 tens = 1e10
```

The bulk modulus (in Pa), shear modulus, angle of internal friction, cohesion and tensile strength are specified. You see that very high cohesion and tensile strength values are given. These are only initial values that are used during the development of gravitational stresses within the body. In effect, we are forcing the body to behave elastically during the development of the initial in-situ stress state.* This prevents any plastic yield during the initial loading phase of the analysis. The reasons for this will become obvious once you gain experience with the explicit simulation procedure.

For this problem, loading is due to gravity. To apply gravity, use the commands

```
set grav 0, 0, -9.81
ini dens = 1000
```

A gravitation acceleration vector of 9.81 m/sec^2 is applied in the negative z-direction. (Gravity is taken as positive in a positive axis direction.) In order to develop a gravitational body force, the

---

* There are several ways to establish an initial stress state for an analysis. For example, an elastic model (**MODEL elastic**) could initially be used to set up the virgin stresses, followed by a change to the Mohr-Coulomb model prior to any excavation, applied loads, or other alterations to the model. A special command, **SOLVE elastic**, which performs this two-step calculation automatically, is also available.

mass density must also be initialized. The **INI** command is used to initialize the mass density to 1000 kg/m^3 for all zones in the model.*

Next, the boundary conditions for the problem are set. At the `Flac3D>` prompt, type

```
fix x range x -0.1 0.1
fix x range x 5.9 6.1
fix y range y -0.1 0.1
fix y range y 7.9 8.1
fix z range z -0.1 0.1
```

With these commands, roller boundaries are placed on five sides of the model. The boundaries are "fixed" only in the specified direction (i.e., no displacement or velocity is allowed). The **FIX** commands perform the following functions.

1. The gridpoints along the boundary planes at $x = 0$ and $x = 6$ are fixed in the x-direction. These two planes fall within the coordinate ranges specified by the **range** keywords for the first two **FIX** commands.

2. The gridpoints along the boundary planes at $y = 0$ and $y = 8$ are fixed in the y-direction. These planes fall within the ranges specified for the third and fourth **FIX** commands.

3. The gridpoints along the bottom boundary ($z = 0$) are fixed in the z-direction. This plane falls within the range for the fifth **FIX** command.

We wish to monitor the change in the values of selected variables in the model during the calculational stepping. A **HISTORY** command can assist determining whether a stable equilibrium solution or unstable collapse is occurring. We type the commands

```
hist  n = 5
hist unbal
hist gp zdisp 4,4,8
```

We choose to monitor the change in variables every five calculation steps. (The default is every ten steps.) The selected values are then stored in a history array at every fifth step. Two variables are monitored: the maximum unbalanced force, and the z-displacement at gridpoint ($x = 4$, $y = 4$, $z = 8$). It is always a good idea to monitor the maximum unbalanced force in a model. If the unbalanced force approaches a very small value and displacement histories become constant, this indicates that an equilibrium state is reached.

Now, we are ready to bring the model to an initial equilibrium state. Because *FLAC^{3D}* is an explicit dynamic code, we step the model through "time,"† allowing the kinetic energy of the mesh to damp

---

* Note that it is only necessary to specify density if gravitational loading is applied to a *FLAC^{3D}* model. For static analyses not involving gravity, density is not required. (This differs from two-dimensional *FLAC*.)

† calculation time — not real time

out (thus providing the static solution we seek). To allow gravitational stresses to develop within the body, we timestep the simulation to equilibrium. Here the **SOLVE** command is used to detect equilibrium automatically.

Type the commands

```
set mech force=50
solve
```

The calculation process will begin, and the timestep number and maximum unbalanced force will be displayed on the screen. When the unbalanced force falls below the limiting value (a limiting force of 50 N is specified with the **SET** command), the run will stop.* The plots are updated, since they are still visible on the screen. Shutting down the plots will cause the model to cycle faster.

For our model, the calculation stops at step 351.† On a 2.8 GHz Pentium 4 computer, this calculation takes approximately 2 seconds.

We can verify that equilibrium is reached by examining the histories of the unbalanced force and z-displacement. Type

```
plot
hist 1
```

for the unbalanced force history (see Figure 2.3). Press <ENTER> to return to the command prompt and then type

```
hist 2
```

for the z-displacement history (see Figure 2.4). The unbalanced force history approaches zero, and the displacement history becomes constant; both are indicators that an equilibrium state has been reached.

The last two plots were displayed on *FLAC3D*'s base view (`Base/0`). Any plot items not explicitly **add**ed to a view are displayed immediately on the base view. This has no effect on any other created view — the base view is simply a sort of "scratch" view where plots can be examined quickly.

---

* The selection of solution limits is discussed later in Section 2.7.4.

† The step number at which this calculation stops may vary slightly, depending upon the precision limits of your co-processor.

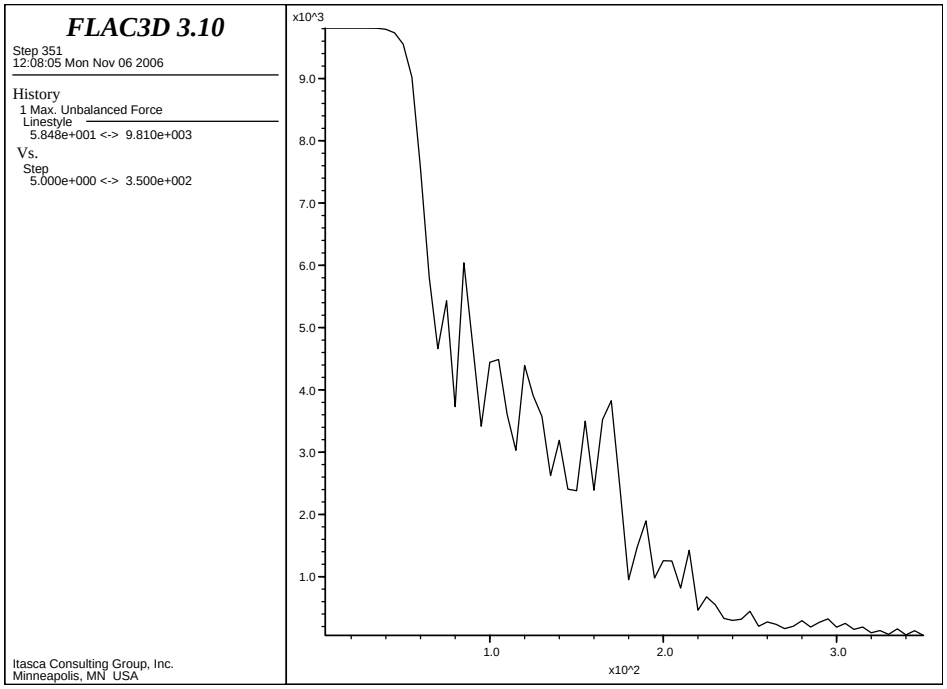

Figure 2.3 Maximum unbalanced force history

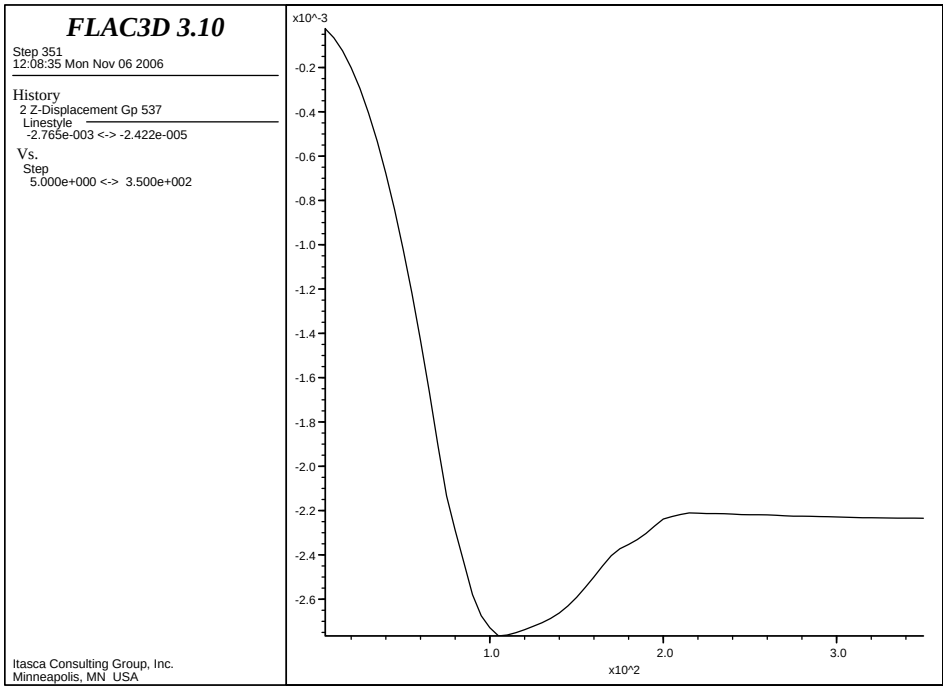

Figure 2.4 z-displacement history at (x = 4, y = 4, z = 8)

Note that each history is numbered sequentially from 1 as it is entered via the **HIST** command. Return to the `Flac3D>` prompt and type

```
print hist
```

for a listing of the histories and their corresponding numbers.

It is also possible to examine the gravitational stresses that have developed in the model. Here, we will create a complex view containing a number of plot items:

```
plot create GravV
plot set plane dip=90 dd=0 origin=3,4,0
plot set rot 15 0 20
plot set center 2.5 4.2 4.0
plot add bound behind
plot add bcont szz plane
plot add axes
plot show
```

This sequence will create a view, which we have called `GravV`, and make it the current view. We then set a plane for that view oriented at a dip angle of 90° (from the xy-plane, assuming that negative-z is "down"), a dip direction of 0° (measured clockwise from the positive y-axis in the xy-plane) and with one point on the plane at (x = 3, y = 4, z = 0). We add a wire-frame boundary plotted *behind* the plane, and a block contour plot of the vertical stress component σ_{zz} on the plane. Finally, the model axes are added. The block contour plot, as opposed to an interpolated contour plot, displays the value of the stress calculated at each zone centroid. The color of each zone corresponds directly to the zone-based stress. When **show** is typed, the view we have created is displayed. You should see a perspective view similar to that in Figure 2.5.

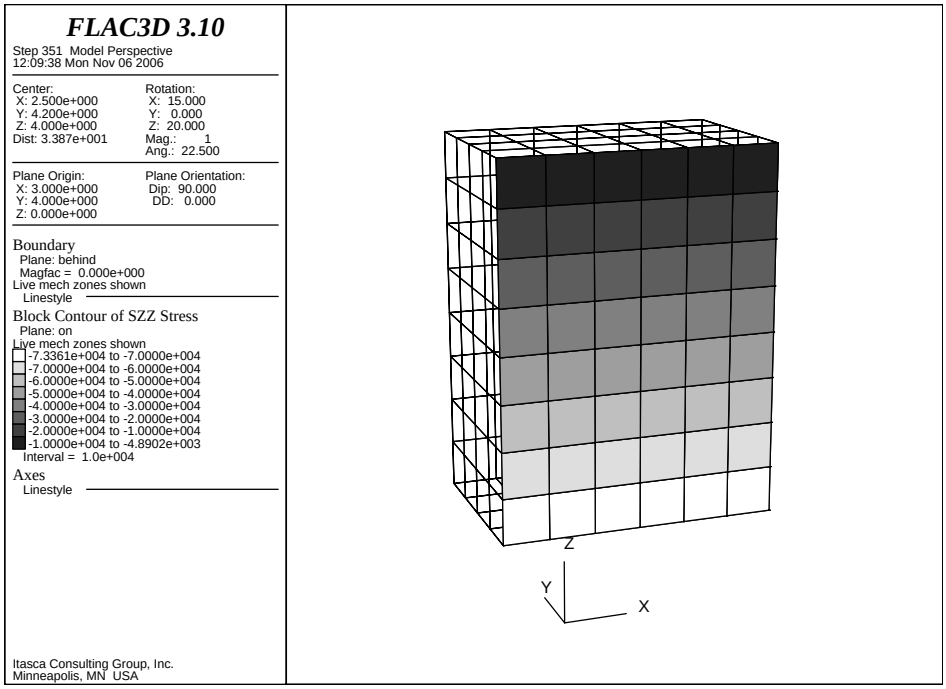

Figure 2.5 Gravitational stress contours at initial equilibrium

It is wise to save the initial state so that you can restore it at any time to perform parameter studies. To save this state, return to the `Flac3D>` prompt and type

```
save trench.sav
```

A save file, “TRENCH.SAV,” will be created on the default drive.

We have now created two plot views of our model. The command

```
plot print
```

will display a list of the views; the active view will be indicated with an arrow. The command

```
plot print view
```

will display details of the current view. Adding a view name or number to the preceding command will produce a detailed description of that view, including all the settings and the plot items on the view. We can change the current view from `GravV` to `Trench` with the command

```
plot current Trench
```

which will cause the view `Trench` to accept setting or item alterations. Any existing view may be plotted directly, without first making it current; the command sequence is

```
plot show <viewname>
```

where viewname is the selected view to be plotted. All available views are also listed as menu items under PLOT on the main menu bar when the command window is active.

Now we can excavate a trench in the soil. First, type

```
prop coh=1e3 tens=1e3
```

This will set the cohesion and tensile strength for all zones to 1000 Pa. These values for strength are high enough to prevent failure in our initial state (i.e., unexcavated), but you should always check for possible failure in the initial state by performing a few calculation steps. To excavate the trench, enter

```
model null range x=2,4 y=2,6 z=5,10
```

The dimensions of the excavation region (i.e., the null material) are defined by the x-, y- and z-coordinate range.

With a low cohesion and vertical unsupported trench walls, collapse should occur. Because we want to examine this process realistically, the large-strain logic is specified. This is done by typing

```
set large
```

For plotting purposes, we wish to see only the change in displacements from the trench excavation, and not from the previous gravitational loading, so we zero out the x-, y- and z-displacement components:*

```
ini xdis=0  ydis=0  zdis=0
```

We purposely set the cohesion low enough to result in failure, so we do not want to use the **SOLVE** command with a limit for out-of-balance force (which checks for equilibrium). Our simulation will never converge to the equilibrium state. Instead, we can step through the simulation process one timestep at a time, and plot and print the results of the collapse as it occurs. This is the real power of the explicit method. The model is not required to converge to equilibrium at each calculation cycle because we never have to solve a set of linear algebraic equations simultaneously, as is the case for implicit codes, with which many engineers are familiar.

In *FLAC3D*, we use the **STEP** command

```
step 2000
```

FLAC3D will now step through 2000 timesteps. (This takes approximately 15 seconds on a 2.8 GHz Pentium 4 computer) Examine the calculation thus far by plotting some results. For example, repeat the plot sequence to produce the rendered contour plot on a plane. But, this time, plot displacement contours. Type the sequence

```
plot
create DispCont
```

---

* This will not affect the calculations, since the model does not require displacement in the calculation process. They are kept only as a convenience to the user.

```
copy GravV DispCont settings
add cont disp plane behind shade on
add axes
show
```

A plot similar to that in Figure 2.6 should appear. We have copied the settings from the previous view (specifically, the plane-orientation settings), since we want to produce comparable plots. We can copy either the view contents or the view settings (or both) from one view to another, allowing us to produce a series of similar views.

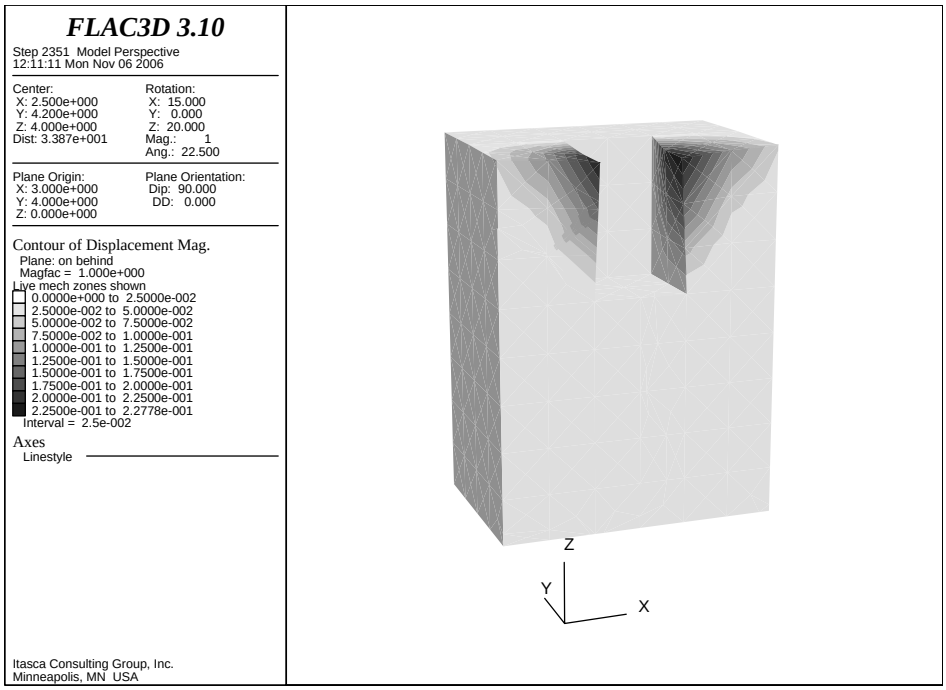

Figure 2.6 Displacement contours at 2000 steps after excavation

You will notice in Figure 2.6, some mesh distortion beginning at the trench. Also, the displacement contours indicate the extent of surface settlement that results from the excavation.*

This ends the initial tutorial. In the following sections in *Getting Started*, we will present other features in *FLAC3D* that can be used to add more complexity to this example, including ways to stabilize the excavation. We recommend that you read the rest of *Getting Started* for a beginner's guide to the mechanics of using *FLAC3D*. As you become more familiar with the code, turn to Section 3.3 for additional details on problem solving with *FLAC3D*.

---

* Note that we have made our boundaries on this problem small, in order to speed operation. Thus, some effect of the boundaries on model results is expected.

2.3 Nomenclature

FLAC3D uses nomenclature that is consistent, in general, with that used in conventional finite difference or finite element programs for stress analysis. The basic definitions of terms are reviewed here for clarification. Figure 2.7 is provided to illustrate the *FLAC3D* terminology.

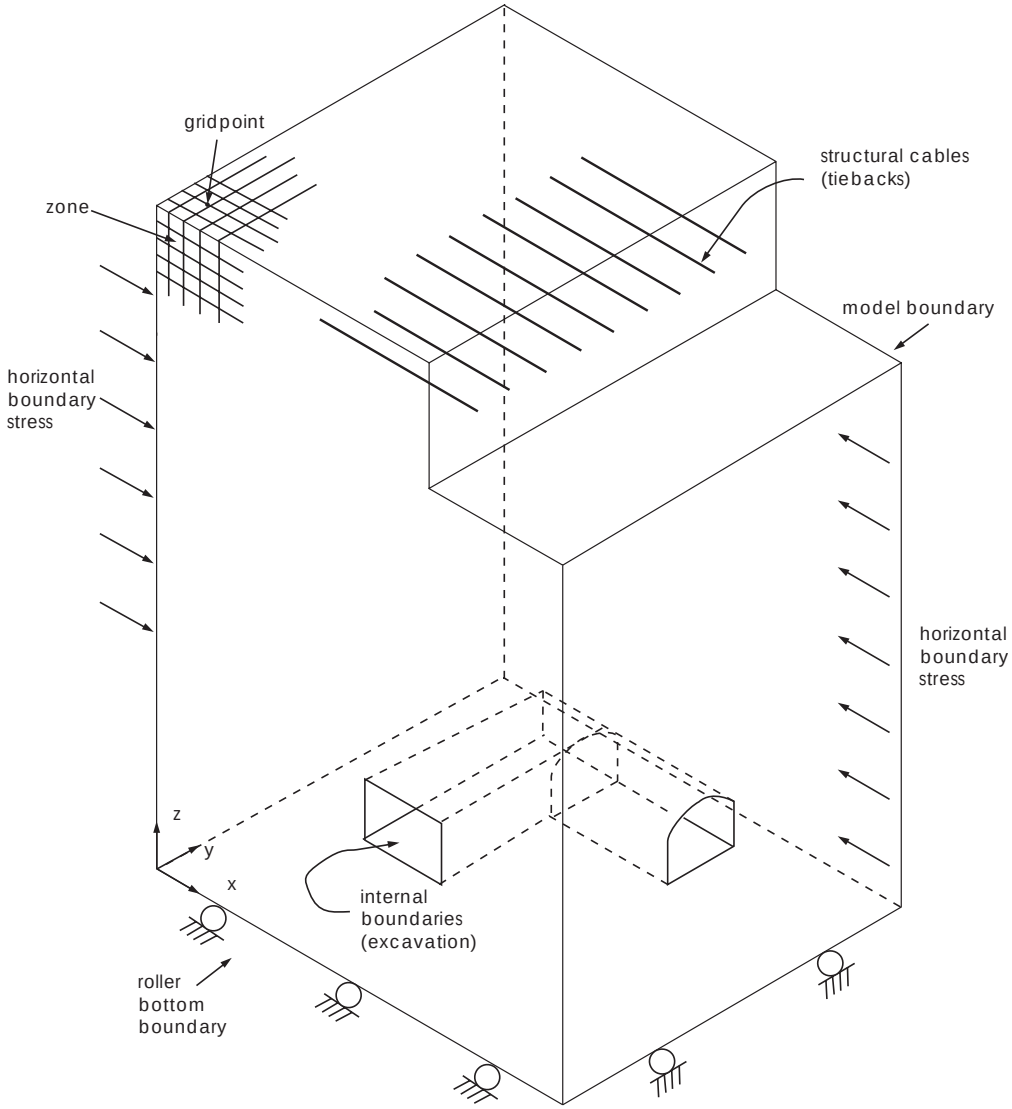

Figure 2.7 Example of a FLAC3D model

FLAC3D MODEL — The *FLAC3D* model is created by the user to simulate a physical problem. When referring to a *FLAC3D* model, the user implies a sequence of *FLAC3D* commands (see Section 1 in the **Command Reference**) that define the problem conditions for numerical solution.

ZONE — The finite difference zone is the smallest geometric domain within which the change in a phenomenon (e.g., stress versus strain) is evaluated. Polyhedral zones of different shapes (e.g., brick, wedge, pyramid and tetrahedral-shaped zones) are used to create models, and can be viewed upon plotting. Each polyhedral zone contains two overlaid sets of five tetrahedral sub-zones, but the user is not normally aware of these. Another term for zone is element.

GRIDPOINT — Gridpoints are associated with the corners of the finite difference zones. There are five, six, seven or eight gridpoints associated with each polyhedral zone, depending on the zone shape. A set of x-, y-, z-coordinates is assigned to each gridpoint, thus specifying the exact location of the finite difference zones. Other terms for gridpoint are nodal point and node.

FINITE DIFFERENCE GRID — The finite difference grid is an assemblage of one or more finite difference zones across the physical region that is being analyzed. Another term for grid is mesh. The finite difference grid also identifies the storage locations of all state variables in the model. The procedure followed in *FLAC3D* is that all the vector quantities (e.g., forces, velocities, displacements) are stored at gridpoint locations, while all scalar and tensor quantities (e.g., stress and material properties) are stored at zone centroid locations.

MODEL BOUNDARY — The model boundary is the periphery of the finite difference grid. Internal boundaries (i.e., holes within the grid) are also model boundaries.

BOUNDARY CONDITION — A boundary condition is the prescription of a constraint or controlled condition along a model boundary (e.g., a fixed displacement or force for mechanical problems, an impermeable boundary for groundwater flow problems, adiabatic boundary for heat transfer problems, etc.).

INITIAL CONDITIONS — This is the state of all variables in the model (e.g., stresses or pore pressures) prior to any loading change or disturbance (e.g., excavation).

CONSTITUTIVE MODEL — The constitutive (or material) model represents the deformation and strength behavior prescribed to the zones in a *FLAC3D* model. Several constitutive models to assimilate different types of behavior commonly associated with geologic materials are available in *FLAC3D*. Constitutive models and material properties can be assigned individually to every zone in a *FLAC3D* model.

NULL ZONE — Null zones are zones that represent voids (i.e., no material present) within the finite difference grid.

SUB-GRID — The finite difference grid can be composed of sub-grids. Sub-grids can be used to create regions of different shapes in the model (e.g., a dam sub-grid can be placed on a foundation sub-grid). Sub-grids are generated separately and then moved together and attached.

ATTACHED FACES — Attached faces are grid faces of separated sub-grids that are attached or joined together. Attached faces must be coplanar and touching, but gridpoints on each face do not have to match. Sub-grids of different zone densities can be attached.

INTERFACE — An interface is a connection between sub-grids that can separate (e.g., slide or open) during the calculation process. An interface can represent a physical discontinuity such as a fault, contact plane, or interface between two different materials.

RANGE — A range in a *FLAC3D* model is a description of a specific volume of space. A range delimits a volume to which a command operation will apply. A range, or element of a range, specified in terms of *x*-, *y*-, *z*-coordinates remains fixed in space even if the model is moving — it is not connected to the zones and gridpoints in the model. A range, or element of a range, specified in terms of groups includes the space inside all the encompassed zones and is connected to the model. An ID number can also be an element of a range, indicating that the range includes, and is connected to, the zone, gridpoint or structural element entity with the specified ID number.

GROUP — A group in a *FLAC3D* model refers to a collection of zones identified by a unique name. Groups are used to limit the range of certain *FLAC3D* commands, such as the **MODEL** command that assigns material models to designated groups. Any command reference to a group name indicates that the command is to be executed on that group of zones.

ID NUMBER — Individual elements of a *FLAC3D* model are identified by identification (ID) numbers. The following model elements have ID numbers: interfaces, gridpoints, zones, volumes, reference points, histories, tables, plot items and structural element entities (i.e., beams, cables, piles, shells, liners and geogrids). These are unique numbers that assist the user in identifying specific elements in a model. The **PRINT** command is used to obtain the ID numbers. ID numbers can be assigned to interfaces, structural element entities, reference points, histories, tables and plot items by the user.

Component identification (CID) numbers are also assigned to individual elements of a structural element entity. A unique CID number is created for each node, element and node/grid link that comprise a beam, cable, pile, shell, liner or geogrid entity.

STRUCTURAL ELEMENT — Two types of structural element are available in *FLAC3D*. Two-noded, linear elements represent the behavior of beams, cables and piles. Three-noded, flat triangular elements represent shells, liners and geogrids. Structural elements are used to simulate the interaction of structural support within a soil or rock mass. Nonlinear material behavior can be represented with the elements.

Each structural element entity (beam, cable, pile, shell, liner or geogrid) is composed of three components: nodes; individual elements (called SELs); and node/grid links. The characteristics of each of these components distinguish the behavior of the beam, cable, pile, shell, liner and geogrid entities.

STEP — Because *FLAC3D* is an explicit code, the solution to a problem requires a number of computational steps. During computational stepping, the information associated with the phenomenon under investigation is propagated across the zones in the finite difference grid. A certain number of steps is required to arrive at an equilibrium (or steady-flow) state for a static solution. Typical problems are solved within 2000 to 4000 steps, although large complex problems can require tens of thousands of steps to reach a steady state. When using the dynamic analysis option, **STEP** refers to the actual timestep for the dynamic problem. Other terms for step are timestep and cycle.

STATIC SOLUTION — A static or steady-state solution is reached in *FLAC3D* when the rate of change of kinetic energy in a model approaches a negligible value. This is accomplished by damping the equations of motion. At the conclusion of the static solution stage, the model will either be at a state of equilibrium or at a state of steady flow of material, if a portion (or all) of the model is unstable (i.e., fails) under the applied loading conditions. This is the default calculation in *FLAC3D*.* Static mechanical solutions can be coupled to transient groundwater flow or heat transfer solutions. (As an option, fully dynamic analysis can also be performed by inhibiting the static solution damping.)

UNBALANCED FORCE — The unbalanced force indicates when a mechanical equilibrium state (or the onset of plastic flow) is reached for a static analysis. A model is in exact equilibrium if the net nodal-force vector (the resultant force) at each gridpoint is zero. The maximum nodal-force vector is monitored in *FLAC3D*, and printed to the screen when the **STEP** or **SOLVE** command is invoked. The maximum nodal force vector is also called the *unbalanced* or *out-of-balance* force. The maximum unbalanced force will never exactly reach zero for a numerical analysis, but the model is considered to be in equilibrium when the maximum unbalanced force is small compared to the total applied forces in the problem. If the unbalanced force approaches a constant nonzero value, this probably indicates that failure and plastic flow are occurring within the model. When a gridpoint is fixed in a given direction, the component of the unbalanced force in that direction is equivalent to the reaction force.

DYNAMIC SOLUTION — For a dynamic solution, the full dynamic equations of motion (including inertial terms) are solved; the generation and dissipation of kinetic energy directly affect the solution. Dynamic solutions are required for problems involving high frequency and short duration loads (e.g., seismic or explosive loading). The dynamic calculation is an optional module for *FLAC3D* (see Section 3 in **Optional Features**).

LARGE STRAIN/SMALL STRAIN — By default, *FLAC3D* operates in small-strain mode: that is, gridpoint coordinates are not changed even if computed displacements are large (compared to typical zone sizes). In large-strain mode, gridpoint coordinates are updated at each step according to computed displacements. In large-strain mode, geometric nonlinearity is possible.

---

* In some finite element (FE) literature, the mistaken notion exists that a dynamic solution method cannot produce a true equilibrium state, compared to an FE solution, which is believed to satisfy perfectly the set of governing equations at equilibrium. In fact, *both* methods only satisfy the equations approximately, but the level of residual errors can be made as small as desired. In *FLAC3D*, the level of error is objectively quantified as the ratio of unbalanced force at a gridpoint to the mean of the set of absolute forces acting at the gridpoint. This measure of error is very similar to the convergence criteria used in FE solutions. In both cases, the solution process is terminated when the error is below a desired value.

2.4 The Finite Difference Grid

The finite difference grid spans the physical domain being analyzed. The smallest possible grid that can be analyzed with *FLAC3D* consists of only one zone. Most problems, however, are defined by grids that consist of hundreds or thousands of zones.

The *FLAC3D* grid is specified in terms of global x-, y- and z-coordinates. All gridpoints and zone centroids are located by their (x,y,z) position vector. A simple cubic grid is shown in Figure 2.8.

Each gridpoint and zone is also identified by an identification number (ID). The ID number and global coordinates for gridpoints can be found by typing

```
print gp position
```

and the zone ID numbers and global coordinates of their centroids can be found by typing

```
print zone
```

Grid generation with *FLAC3D* involves adjusting and shaping the mesh to fit the shape of the physical domain. The generation process is performed via the **GENERATE** command; the recommended procedure for grid generation is discussed in Section 3.3.

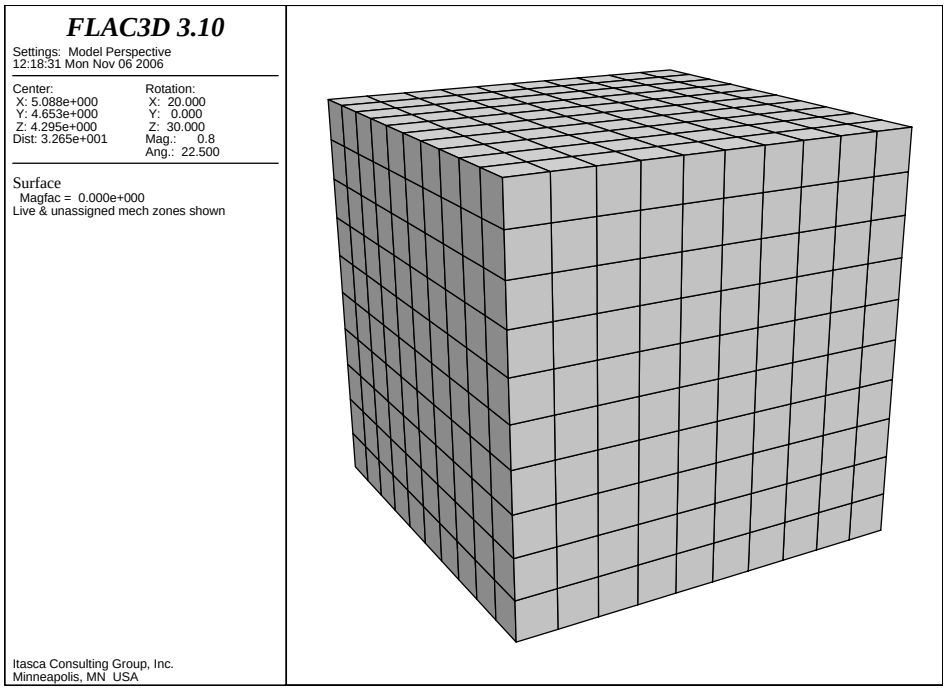

Figure 2.8 Finite difference grid with 1000 zones

2.5 Command Syntax

All input commands* to *FLAC3D* are word-oriented and consist of a primary command word followed by one or more keywords and values, as required. Some commands accept switches — that is, keywords that modify the action of the command. Each command has the following format:

COMMAND **key**word ***value*** . . . <**key**word ***value*** . . . > . . .

Here, optional parameters are denoted by < >, while the ellipses (. . .) indicate that an arbitrary number of such parameters may be given. The commands are typed literally on the command line. You will note that only the first few letters are in bold type. The program requires these letters, at a minimum, to be typed to recognize the command; command input is not case-sensitive. The entire word for commands and keywords may be entered if the user so desires.

Many of the keywords are followed by a series of values which provide the numeric input required by the keyword. The decimal point may be omitted from a real value, but may not appear in an integer value.

Commands, keywords and numeric values may be separated by any number of spaces, or by any of the following delimiters:

( ) , =

A semicolon (;) may be used to precede comments; anything that follows a semicolon in an input line is ignored. It is useful, and strongly recommended, to include comments in data files. Not only is the input documented in this way, the comments are echoed to the output as well, providing the opportunity for quality assurance in your analysis.

A single input line, including comments, may contain up to 80 characters.

If more than 80 characters are required to describe a particular command sequence, then an ampersand (&) can be given at the end of an input line to denote that the next line will be a continuation of that line. A total of 1024 characters per command sequence are allowed.

Please note that the typographical conventions listed in Table 2.2 are used throughout this manual.

---

* The commands and their meanings are presented in Section 1 in the **Command Reference**.

Table 2.2 Typographical conventions

Type style	Used for
BOLD	*FLAC3D* commands and *FISH* statements
bold	*FLAC3D* keywords and *FISH* internal variables and functions
bold	user-defined *FISH* variables and functions
INITIAL CAPS	menu items and buttons with the hot-keys underlined
var	place-holders for variables
PRESS ME	button with the hot-key underlined
<A>	type the key between < > (here, <A>) on the keyboard
<SHIFT-A>	hold down the first key while pressing the second (here, <SHIFT> and the <A> key)

2.6 Named Objects

FLAC3D gives the user the power to create, name and use objects. For example, if a number of plot views are created, they can be given descriptive names like "TopView" or "Velocity_Vectors." In Example 2.2, we created a new plot view, naming it "Trench" in the process. Parts of a model can be given names such as "Excavate_1," which can identify a volume to be removed during an excavation sequence. While the code can certainly be run without using names for objects, the entire process of modeling and reporting can be eased considerably by using these facilities. This section gives some ideas of how named objects can be used, and illustrates the differences between the types of objects in *FLAC3D*.

There are two categories of named objects: first, *macro objects*, which are interpreted before being seen by *FLAC3D*'s command processor; and second, *model objects*, which are interpreted by *FLAC3D*'s command processor. Any command that is entered by the user is first passed to the command pre-processor, where objects belonging in the first category are expanded. The pre-processor creates a string that is then sent to the command interpreter, which directs the actions to be performed by the code. It is at this point that objects belonging in the second category are interpreted. Note that the names of macro and model objects are case-sensitive.

2.6.1 Macro Object

The **MACRO** command allows the user to create macro objects that will be expanded by the command pre-processor. Typically, such an object contains a long, complex string that may be used repeatedly in the model. The pre-processor compares a string of command tokens to the list of defined macros and replaces any matching macro object with its fully expanded contents. The process continues, including the examination of the expanded tokens, until the entire string has been checked. Example 2.4 shows how macros could be used. Note the use of nested macros.

Example 2.4 Using macros

```
macro Pt0 'p0      0  0  0'
macro Pt1 'p1 add 10  0  0'
macro Pt2 'p2 add  0 10  0'
macro Pt3 'p3 add  0  0 10'
macro Model_Size 'size 4 5 6'
macro Big_Brick 'zone brick Pt0 Pt1 Pt2 Pt3 Model_Size'

gen Big_Brick

macro 'Pt0' 'p0 15 15 15'
gen Big_Brick
```

When redefining a macro, as in the last use of the **MACRO** command in Example 2.4, we have to put single quotes around the macro name (as shown). Otherwise, the pre-processor would expand

the name since it has already been defined — not quite the result we intended. The pre-processor skips over quoted strings, leaving them to the command interpreter.

This pre-processing has two effects:

(1) macro objects may be nested (but not recursively); and

(2) the macro object name is removed from the command string.

The implication of this second effect is that if a macro object has the same name as a model object or a code command, that object or command will never be seen by the command interpreter. While the user may elect to do something like this, it is generally inadvisable.

There is a special macro object, the ampersand (&), which indicates a line continuation. In many cases, a single command with all its keywords and data will not fit on one input line. Example 2.5 demonstrates how command lines could be broken. The command pre-processor locates any ampersands, concatenates the strings on either side, and passes one long string to the command interpreter. The maximum length of such an expanded string is 1024 characters.*

Example 2.5 Using line continuations

```
gen zone brick p0  0  0  0   &
               p1 10  0  0   &
               p2  0 10  0   &
               p3  0  0 10   &
               size 4 5 6
```

Macros cannot contain multi-line arguments. If an ampersand (&) character is used in a macro, the command pre-processor will tag the line as having a continuation when that macro is used. Anything on the line following the macro use will be taken as part of the current command. This could cause difficulty and should be avoided. If you find you need multiple lines, write a *FISH* function.

2.6.2 Model Object

Model objects such as ranges in space, groups of zones in a model, or plot views can be given user-defined names. Those objects can then be referred to by their names, wherever the identification of such objects is needed by the code, and are processed directly by the code when their names are used. A routine use of the **GROUP** command is to identify (i.e., name) parts of the grid which are to be excavated at some stage in the modeling process. The null constitutive model can then simply be applied to the zones identified by that group name. Execute Example 2.6 for a demonstration of this.

---

* If this proves to be restrictive, the length of this string may be increased in later versions of *FLAC3D*.

Example 2.6 Using a named model object

```
gen zone brick size 6 6 6
group Tunnel range x 1 5 y 0 6 z 1 5
model mohr
.
.
model nul range group Tunnel
.
```

The named *range* and the named *group* are two very different model objects. The range pertains to a specified volume of space (or range of values), whereas the group identifies a collection of finite difference zones in the model. For example (and since geo-engineering involves digging holes), the planet Earth can be viewed as a range (**RANGE Earth** . . .) in space within which we can place a structure (**GROUP Shaft** . . .) which would be a group in our model. It does not matter where in the range named **Earth** the group **Shaft** is placed; the range retains its geometric attributes. In Example 2.7,* we have created a simple 2-layered geology with ranges named “Layer1” and “Layer2.” We have created two macros, “Sand” and “Clay,” which define our soil properties. Our model contains two groups: “Tunnel,” for the group which will be excavated at some point; and “Matrix,” which represents the rest of the model around the tunnel. The macros are used to clearly identify the type of soil we are assigning to our stratigraphy, while the intersections of our groups with the stratigraphy ensure that the appropriate zones take on the appropriate properties. Do not worry about the details of the commands used here; they will all be covered later in this section and in Section 3. The commands related to naming objects are in **`boldface`** for easy identification.

Example 2.7 Illustrating the behavior of* RANGE, GROUP *and* MACRO *model objects

```
; generate the model geometry
gen zone radc          &
  dim   3  3  3  3     &
  ratio 1  1  1  1.2   &
  size  3  8  8  5     &
  edge 10              &
  p0  100 95 100       &
  fill
gen zone reflect dip 90 dd 90 ori 100 100 100
gen zone reflect dip  0 dd  0 ori 100 100 100
;
; naming fixed GROUPS within the model, which will stay
; with the model as the model is moved through space
; - made to represent physical model components here...
```

* The file “NAMES.DAT” contains a version of Example 2.7 that will create plot views to allow the user to see the development of this model.

```
group Tunnel range cylinder end1 100 105 100 end2 100 95 100 radius 3
group Matrix range group Tunnel not
;
; naming RANGES that are fixed in space and unrelated
; to the model geometry - represents stratigraphy...
; (this is a two-layer system split on a horizontal plane
; through the origin)
range name Layer1 plane dip 0 dd 0 ori 0 0 0 above
range name Layer2 plane dip 0 dd 0 ori 0 0 0 below
;
; using MACROS to create soil types as defined by their
; material properties - this is completely independent of
; their location in space...
macro Sand 'bulk 1e8 shear 0.5e8 coh 0 tens 0 fric 35'
macro Clay 'bulk 1e7 shear 0.3e7 coh 1e7 tens 0 fric 0'
;
; bring the model to the axes origin...
; (change these coordinates if you want to see the grid positioned
; elsewhere within the region - remember the model is 10*10*10m)
ini x add -100 y add -100 z add -100
;
; we specify material models according to GROUP...
mo null range group Tunnel
mo mohr range group Matrix
;
; ... and soil properties (via the MACRO names) to whatever parts
; of the model coincide with our stratigraphy (defined with RANGE)...
prop Sand range Layer1
prop Clay range Layer2
```

2.6.3 General Advice

The user is encouraged to view objects as entities that can be used (nouns), rather than entities that do something (verbs). For example, as shown in Example 2.8, if the **GENERATE** command is included in the macro definition of **Big_Brick**, it is quite likely that **Big_Brick** will be used as a noun in one instance, and a verb in another.

Example 2.8 Using macros

```
macro Pt0 'p0      0  0  0'
macro Pt1 'p1 add 10  0  0'
macro Pt2 'p2 add  0 10  0'
macro Pt3 'p3 add  0  0 10'
macro Model_Size 'size 4 5 6'
```

```
macro Big_Brick 'gen zone brick Pt0 Pt1 Pt2 Pt3 Model_Size'
;
Big_Brick
.
.
macro 'Pt0' 'p0 15 15 15'
gen Big_Brick       ; this will cause an error
.
```

New commands (i.e., verbs) can be created with macros. For example, the **PLOT add** sequence can be replaced by the shorter sequence **PA** — see Example 2.9. Note that we have not mixed any nouns into this definition.

Example 2.9 Creating new commands

```
macro PA 'plot add'
.
.
PA history 1 ...
.
```

Mixing uppercase and lowercase in object names will prevent the accidental use of *FLAC3D* commands or keywords. Remember that macro names take precedence over range names and commands.

It is possible to use a range, a group or a macro object to achieve the same result. Example 2.10 shows how each of these could be used in identifying a part of a model to which a property value is assigned.

Example 2.10 Using different object types to do the same job

```
    using a RANGE object ...
range name Big_Brick x = (-3,3) y = (-2,2) z = (-1,1)
model null range Big_Brick

    using a GROUP object ...
group Big_Brick range x = (-3,3) y = (-2,2) z = (-1,1)
model null range group Big_Brick

    using a macro object ...
macro Big_Brick 'x = (-3,3) y = (-2,2) z = (-1,1)'
model null range Big_Brick
```

Notice that the **GROUP** command uses a **range** keyword in the creation of the group object called "Big_Brick." The only difference between the **RANGE** command and the **range** keyword is that the command can be issued on a line of its own, allowing the user to create a number of range objects directly. Otherwise, a range can be used as a part of a command and named at the same time. Example 2.11 illustrates the different techniques. All of this is aimed at providing powerful, flexible tools for model construction.

Example 2.11 Creating named ranges

```
    naming as a RANGE command ...
range name Big_Brick x -3 3 y -2 2 z -1 1
model elastic range Big_Brick
prop bulk 1e8 shear 1e8 range Big_Brick

    using the first RANGE keyword to name the object ...
model elastic range name Big_Brick x -3 3 y -2 2 z -1 1
prop bulk 1e8 shear 1e8 range Big_Brick
```

Named ranges are particularly useful in plotting. Named groups should be used when a specific collection of zones needs to be addressed, whether they manage to remain at their original coordinates throughout the modeling process or not. Think of components of the model as groups, and the space they occupy as ranges.

2.7 Mechanics of Using *FLAC3D*

FLAC3D is based upon a command-driven format because most analyses require the use of data input files. Word commands control the operation of the program. Graphical controls are available where user-interaction is potentially more desirable, specifically in the plotting. This section provides an introduction to the basic commands a new user needs to perform simple *FLAC3D* calculations. If you have not done so already, run the tutorial problem in Section 2.2 for an example of a command-driven analysis with *FLAC3D*.

The tutorial problem — a trench excavated in a soil with low cohesion — is used here to demonstrate the general solution procedure. The procedure can be divided into distinct stages, as illustrated in Figure 2.9. Each stage is discussed separately. Example commands are provided to illustrate each analysis step.

In order to set up a model to run a simulation with *FLAC3D*, three fundamental components of a problem must be specified:

(1) a finite difference grid;

(2) constitutive behavior and material properties; and

(3) boundary and initial conditions.

The grid defines the geometry of the problem. The constitutive behavior and associated material properties dictate the type of response the model will display upon disturbance (e.g., deformational response due to excavation). Boundary and initial conditions define the in-situ state (i.e., the condition before a change or disturbance in the problem state is introduced).

After these conditions are defined in *FLAC3D*, the initial equilibrium state is calculated for the model. An alteration is then made (e.g., excavate material or change boundary conditions), and the resulting response of the model is calculated. The actual solution of the problem is different for an explicit finite difference program like *FLAC3D* than it is for conventional implicit-solution programs. (See the background discussion in Section 1 in **Theory and Background**.) *FLAC3D* uses an explicit time-marching method to solve the algebraic equations. The solution is reached after a series of computational steps. In *FLAC3D*, the number of steps required to reach a solution can be controlled automatically by the code *or* manually by the user. However, the user ultimately must determine if the number of steps is sufficient to reach the solved state. The way this is done will be covered later, in Section 2.7.4.

The general solution procedure, illustrated in Figure 2.9, is convenient because it represents the sequence of processes that occurs in the physical environment. The basic *FLAC3D* commands needed to perform simple analyses with this solution procedure are described below.

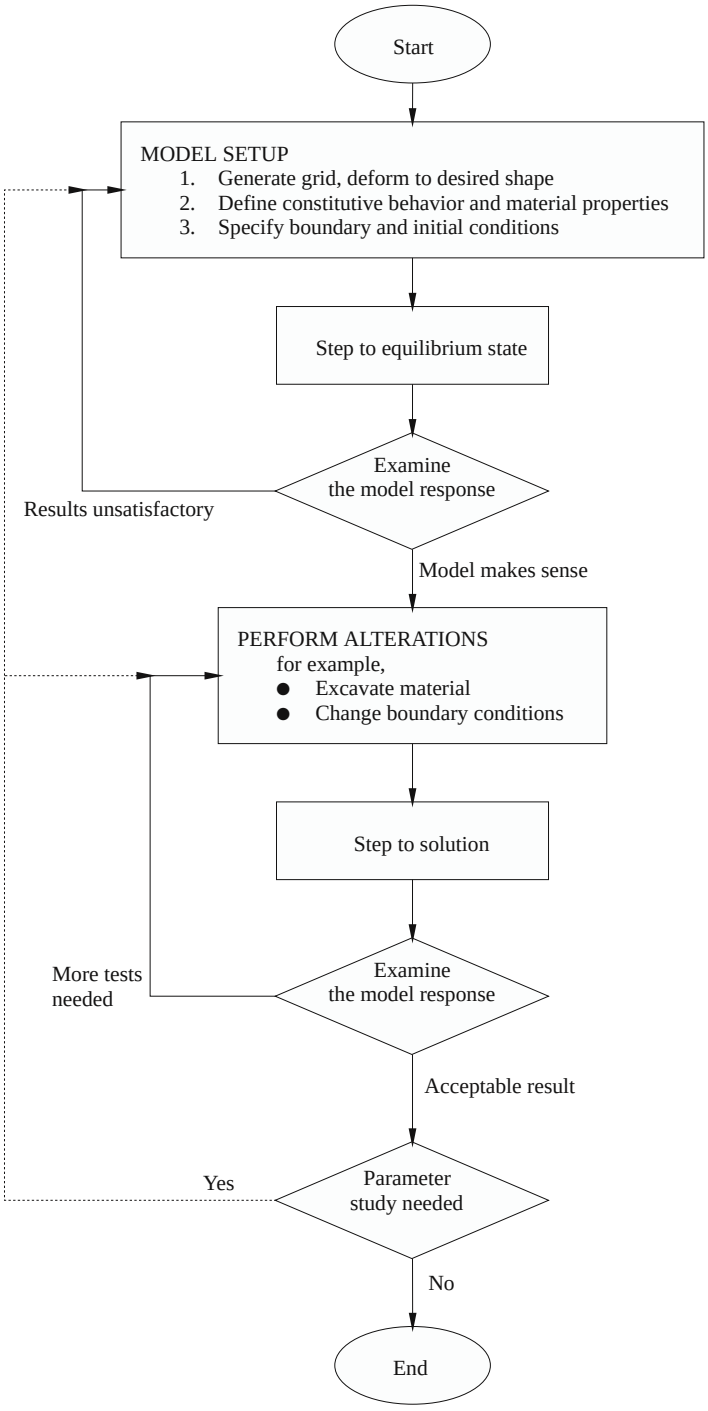

Figure 2.9 General solution procedure

2.7.1 Simple Grid Generation

Grid generation is performed via the **GENERATE** command and associated keywords that both define the number of zones in a model and shape the grid to fit a specified problem region.

Several primitive shapes are built into the generator to expedite mesh generation for simple problem shapes. These include brick, wedge, pyramid and cylinder shapes. Example 2.12 illustrates the command used in the tutorial problem to create a brick-shaped grid containing six zones in the x-direction, eight zones in the y-direction, and eight zones in the z-direction.*

Example 2.12 Generating a simple brick element

```
gen zone brick size 6,8,8
plot surf
```

The number of zones is specified by the **size** keyword. Be careful when selecting the number of zones for a model, because a balance must be struck between the accuracy required and the solution speed. Although there are many aspects of the numerical model that affect the calculation speed, once the basic parameters are defined, the speed varies directly as a function of the number of elements. As a rule-of-thumb, models containing up to roughly 5000 elements will typically reach a solution state for a given alteration in approximately 2000 to 4000 steps. On a 4 GHz Pentium 4 computer, the runtime for a 5000 element model to perform 4000 steps is roughly 5 minutes. Check the speed of calculation on your computer for the specific model, to estimate the runtime required.

It is best to start with a grid that has few zones (say, 1000 to 1500) to perform simple test runs and make refinements to the grid. Then, increase the number of zones to improve the accuracy.

In its simplest form, the **GENERATE** command can supply new coordinates to a grid. For example, assume that the actual coordinates of the trench model run from -10.0 to 10.0 in the x-direction, -10.0 to 10.0 in the y-direction, and −20.0 to 0.0 in the (vertical) z-direction. Example 2.3 shows how this would be specified.

---

* If you want to try entering the command examples interactively, type **NEW** each time you start a new example. This will initialize *FLAC3D* without having to exit and reload the program for a new model. Enter the **PLOT** mode after typing each example, to view the result.

Example 2.13 Using actual coordinates

```
gen zone brick size 6,8,8 p0 -10, -10, -20 &
                          p1  10, -10, -20 &
                          p2 -10,  10, -20 &
                          p3 -10, -10,   0
plot surf
```

In Example 2.13, **p0**, **p1**, **p2** and **p3** are keywords that denote four of the corners of a standard *FLAC3D* mesh (see Figure 2.10). You will notice that an ampersand (&) is given at the end of the first line of the **GEN** command. This denotes that the next line is a continuation of the same command.

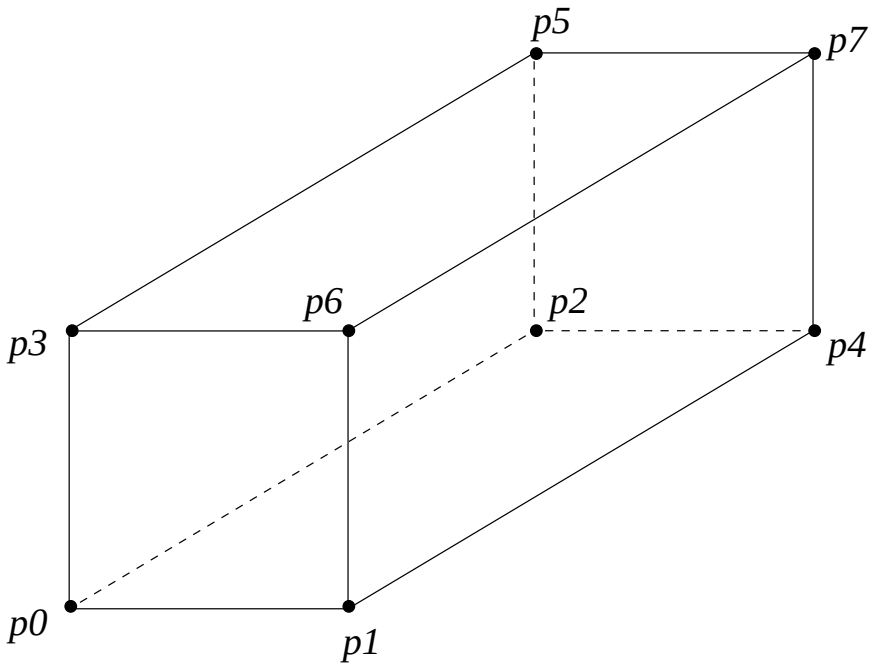

Figure 2.10 Corner coordinate keywords for a standard FLAC3D mesh shape

Only four corners are required to define a parallelepiped-shaped mesh. More corners can be specified to define an irregular surface. Example 2.14 shows how to make a sloping surface at the top of the mesh.

Example 2.14 A sloping surface at the top of a mesh

```
gen zone brick size 6,8,8   p0 -10, -10, -20 &
          p1  10, -10, -20  p2 -10,  10, -20 &
          p3 -10, -10,   0  p4  10,  10, -20 &
          p5 -10,  10,  10  p6  10, -10,   0 &
          p7  10,  10,  10
plot surf
```

The coordinates corresponding to the keywords **p0**, **p1**, **p2**, **p3**, **p4**, **p5**, **p6** and **p7** can be located at arbitrary points in space. However, the eight corners must have the topological sense shown in Figure 2.10 (i.e., **p0**, **p1**, **p2**, **p3** must form a right-handed system) to create positive zone volumes. Non-coplanar faces are permitted, but they should be avoided if possible because a small volume error may be introduced.

In the tutorial example, we noted that the boundaries of the model were influencing the results (see Figure 2.6). The boundary must be placed far enough away from the excavation to reduce these effects. A gradually graded mesh can be created in *FLAC3D* to move the model boundaries farther out without significantly increasing the number of zones. For example, the command **GEN zone radbrick** creates a radially graded mesh around a brick-shaped mesh. The command in Example 2.15 creates a $3 \times 5 \times 5$ zone brick-shaped mesh surrounded by a 7-zone radially graded mesh.

Example 2.15 Combining a regular and a radially graded mesh

```
gen zone radbrick &
    p0 (0,0,0)  p1 (10,0,0)  p2 (0,10,0)  p3 (0,0,10) &
    size  3,5,5,7   &
    ratio 1,1,1,1.5 &
    dim  1 4 2 fill
plot surf
```

The *x,y,z* coordinate system in *FLAC3D* is always right-handed and, as a default, the z-axis is drawn in the vertical direction on the screen. In Example 2.14, we assumed the z-axis was pointing in the vertical direction. However, we do not have to interpret the z-axis to mean the up direction. For Example 2.15, we will assume that the y-axis is the vertical direction. As long as we define the model in a right-handed system, we can create the grid in any direction we desire.

The **size** keyword, as used in Example 2.15, specifies the number of zones in the brick, and the number radially surrounding the brick (see Figure 2.11). The keyword **ratio** is given to manipulate the grid spacing. The four values that follow **ratio** are geometric ratios between successive zone sizes. The first three values are ratios for the zones in the brick, and the fourth value is the ratio for the zones surrounding the brick. In Example 2.15, the ratio is 1.0 for the brick zones and 1.5 for the zones surrounding the brick. This causes each successive ring of zones surrounding the brick to be 1.5 times larger in the radial direction. The **dim** keyword defines the dimensions of the brick

region (i.e., 1 m × 4 m × 2 m). The **fill** keyword fills the brick region with zones. If **fill** is omitted, no zones will be generated within the brick region.

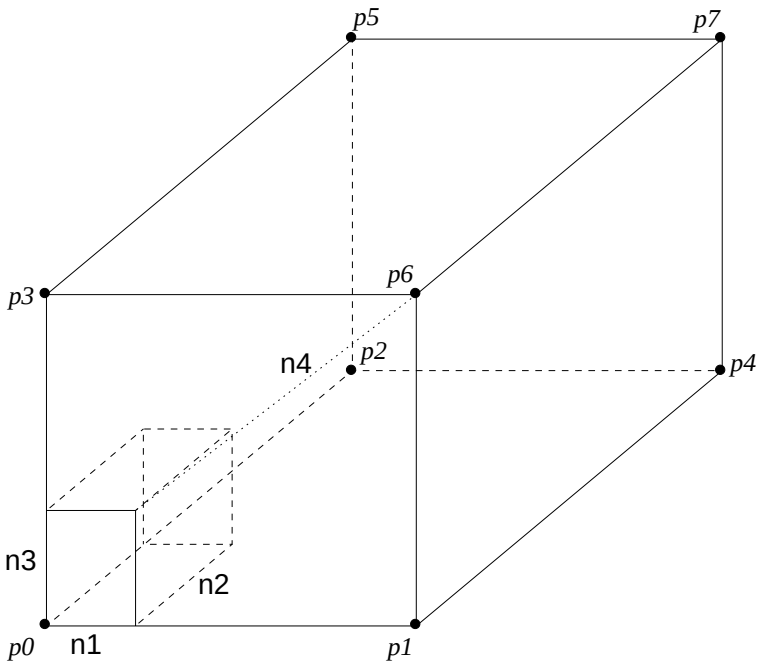

Figure 2.11 Element numbering for a radially graded mesh around brick (size n1 n2 n3 n4)

Several **GENERATE** commands can be given to create different regions of a model. For example, the **GENERATE** command in Example 2.15 creates one-quarter of the trench model. Example 2.16 shows how a series of **GENERATE** commands can be given to create the entire model.

Example 2.16 Combining GEN commands

```
gen zone radbrick &
         p0 (0,0,0)  p1 (10,0,0)  p2 (0,10,0)  p3 (0,0,10) &
         size 3 5 5 7                                      &
         rat 1 1 1 1.5                                     &
         dim 1 4 2 fill
gen zone radbrick &
         p0 (0,0,0)  p1 (0,0,10)  p2 (0,10,0)  p3 (-10,0,0) &
         size 5 5 3 7                                       &
         rat 1 1 1 1.5                                      &
         dim 2 4 1 fill
gen zone radbrick &
         p0 (0,0,0)  p1 (-10,0,0)  p2 (0,10,0)  p3 (0,0,-10) &
         size 3 5 5 7                                        &
```

```
          rat 1 1 1 1.5                                          &
          dim 1 4 2 fill
gen zone radbrick &
        p0 (0,0,0)  p1 (0,0,-10)  p2 (0,10,0)  p3 (10,0,0) &
        size 5 5 3 7                                           &
        rat 1 1 1 1.5                                          &
        dim 2 4 1 fill
plot surf lblue
```

Notice that **size**, **ratio** and **dim** all refer to local axes as defined by **p0, p1, p2, p3** in Figure 2.11, *not* to the global x,y,z-axes. The values will change, depending on the specification of **p0**, **p1**, **p2** and **p3**. The radially graded trench model is shown in Figure 2.12. Be sure that *all* gridpoints match at boundaries between shapes. Errors will occur in your analysis if gridpoints of connected shapes are not at the same locations along boundaries. Refer to Section 3 for further discussion on the creation of meshes and the proximity tolerances of adjacent gridpoints.

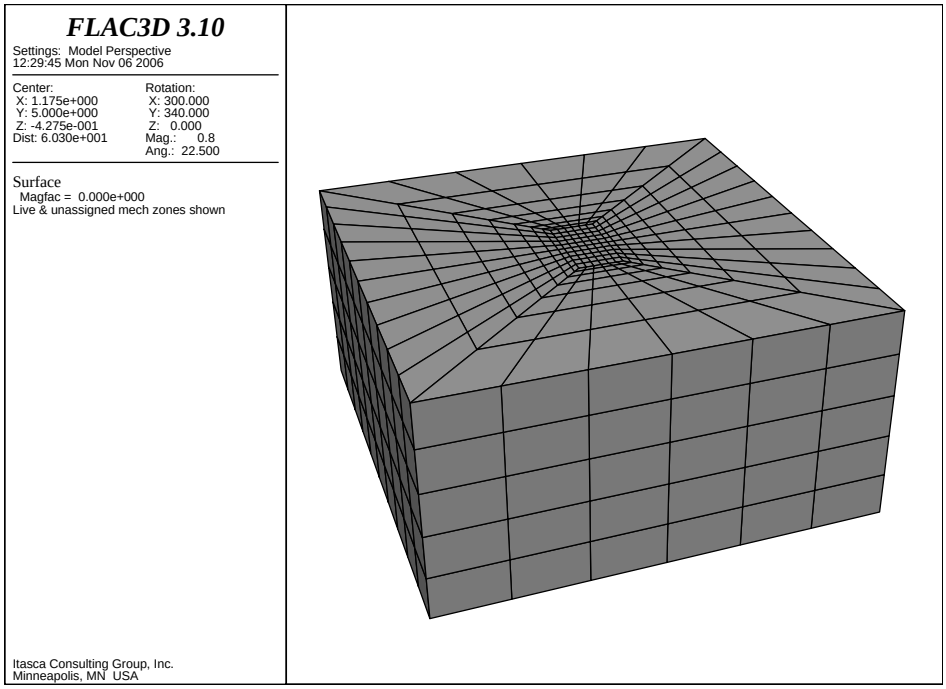

Figure 2.12 Radially graded trench model

Example 2.16 serves to illustrate the requirement of accurate mapping of adjacent elements in *FLAC3D*. There are other ways to achieve the same result shown in Figure 2.12, since we can take advantage of planes of symmetry. Parts of the model can be reflected about specified planes to produce a larger model. Example 2.17 shows how this can be achieved.

Example 2.17 Creating a model by reflecting elements on planes of symmetry

```
gen zone radbrick  &
         p0 (0,0,0)  p1 (10,0,0)  p2 (0,10,0)  p3 (0,0,10)  &
         size  3,5,5,7   &
         ratio 1,1,1,1.5 &
         dim 1 4 2 fill
gen zone reflect dip  0 dd 90
gen zone reflect dip 90 dd 90
plot surf
```

When selecting a value for the geometric ratio, there are a number of criteria that should be considered.

- Finer meshes lead to more accurate results in that they provide a better representation of high stress gradients.
- Accuracy increases as zone aspect ratios tend to unity.
- If different zone sizes are needed, a more gradual change from the smallest to the largest will improve the results; abrupt changes in zone size should be avoided.

However, as the mesh is made finer and the number of zones increase, more RAM is required and the computation time lengthens. Improving the mesh geometry by adjusting the zone size will certainly improve RAM efficiency and will reduce computation time. It will also take some time to plan and set up. Moving from a "brute force" approach (i.e., single-sized elements in a *large* uniform mesh) to a more elegant solution will improve RAM use and calculation speed when dealing with a more complicated geometry. Methods to assist with grid generation are discussed in Section 3.3.

2.7.2 Assigning Material Models

Once the grid generation is complete, one or more material models and associated properties must be assigned to all zones in the model. This is done by using two commands: **MODEL** and **PROPERTY**. *FLAC3D* has twelve built-in material models (described in Section 2.1 in **Theory and Background**). Three models are sufficient for most analyses the new user will make: **MODEL null**, **MODEL elastic**, and **MODEL mohr**.

MODEL null represents material which is removed or excavated from the model. **MODEL elastic** assigns isotropic elastic material behavior. **MODEL mohr** assigns Mohr-Coulomb plasticity behavior.

MODEL elastic and **MODEL mohr** require that material properties be assigned via the **PROPERTY** command. For the elastic model, the required properties are bulk and shear modulus.

NOTE: Bulk modulus, K, and shear modulus, G, are related to Young's modulus, E, and Poisson's ratio, ν, by the following equations:

$$K = \frac{E}{3(1-2\nu)} \tag{2.1}$$

$$G = \frac{E}{2(1+\nu)} \tag{2.2}$$

or

$$E = \frac{9KG}{3K+G} \tag{2.3}$$

$$\nu = \frac{3K-2G}{2(3K+G)} \tag{2.4}$$

For the Mohr-Coulomb plasticity model, the required properties are:

(1) bulk and shear moduli;

(2) friction and dilation angles;

(3) cohesion; and

(4) tensile strength.

If any of these properties is not assigned, its value is set to zero by default.

Zones may be assigned different material models. For example, an elastic model may be prescribed for the upper half of a 10 m × 10 m × 10 m grid, and a Mohr-Coulomb model for the lower half of the grid. Example 2.18 shows how this is done using range coordinates. Incidentally, note the use of the **MACRO** command in labeling soil types. The **range** keyword and parameters could have been included within the macro. However, keeping the properties and geometry separate makes good sense: we can use the same macros to apply those material properties anywhere in our model. We will be discussing similar naming strategies related to the geometry shortly.

Example 2.18 Assigning different material models in different areas of a single grid

```
gen zone brick size 10,10,10
macro SiltySand 'bulk 1.5e8 shear 0.3e8'
macro ClayeyGravel ' bulk 1.5e8 shear 0.6e8 fric 30 coh 5e6 ten 8.66e6'
; elastic in upper half of grid
model elas range z=5,10
prop SiltySand range z=5,10
; mohr-coulomb in lower half
model mohr range z=0,5
prop ClayeyGravel range z=0,5
plot block model lmagenta lgreen
```

Instead of using global coordinates with each **range** keyword, a range can be defined and named with the **RANGE** command. The named range can then be used as a parameter for the **range** keyword. This is demonstrated in Example 2.19, where we first identify and name a range with the **RANGE** command, followed by the use of that named range in applying a material model.

Example 2.19 Creating and using a named range

```
gen zone radbrick  &
         p0 (0,0,0)  p1 (10,0,0)  p2 (0,10,0)  p3 (0,0,10)  &
         size  3,5,5,7   &
         ratio 1,1,1,1.5 &
         dim 1 4 2 fill
gen zone reflect dip  0 dd 90
gen zone reflect dip 90 dd 90
;
; identify the trench
range name trench x=-1,1 y=0,4 z=-2,2
;
; excavate the trench
model null range trench
plot surf lblue
```

The trench excavation for the model shown in Figure 2.12 is plotted in Figure 2.13. Note that the excavation can be filled by material of any constitutive model, with properties appropriate to the model.

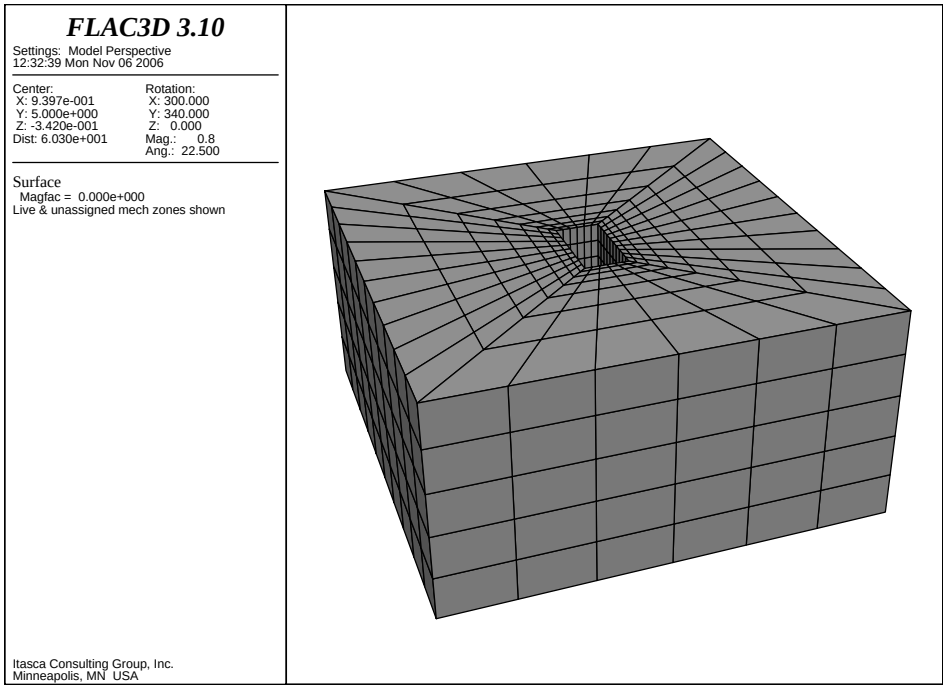

Figure 2.13 Radially graded trench model with trench excavated

2.7.3 Applying Boundary and Initial Conditions

After the grid is generated, boundary and initial conditions are applied. Boundary conditions are normally specified with the **APPLY** and **FIX/FREE** commands, and initial conditions are assigned with the **INITIAL** command. Table 2.3 provides a summary of common boundary-condition commands and their effects. Table 2.4 provides a similar table for initial condition commands.

The boundary conditions in a numerical model consist of the values of field variables that are prescribed at the boundary of the numerical grid. Note that by using a boundary condition command, a condition or constraint that will not change while *FLAC3D* is calculating a solution (unless specifically changed by the user) is imposed. Boundaries can be either real or artificial — real boundaries exist in the physical object being modeled, whereas artificial boundaries are introduced to enclose the chosen number of zones.

Artificial boundaries fall into two categories: planes of symmetry and planes of truncation. A symmetry plane takes advantage of the fact that the geometry and loading in a system are symmetrical about one or more planes. A truncation plane is a boundary sufficiently far from the area of interest that the behavior in that area is not greatly affected. It is important to know how far away to place these boundaries, and what errors they might precipitate in the stresses and displacements computed for the area of interest.

Table 2.3 Summary of common boundary-condition commands

COMMAND		EFFECT
		Gridpoint Condition:
APPLY	**xforce**	x-component of force applied at boundary gridpoints
	xvelocity	x-velocity applied at boundary gridpoints
	yforce	y-component of force applied at boundary gridpoints
	yvelocity	y-velocity applied at boundary gridpoints
	zforce	z-component of force applied at boundary gridpoints
	zvelocity	z-velocity applied at boundary gridpoints
		Face Condition:
	sxx	xx-component of total stress tensor applied at boundary faces
	sxy	xy-component of total stress tensor applied at boundary faces
	sxz	xz-component of total stress tensor applied at boundary faces
	syy	yy-component of total stress tensor applied at boundary faces
	syz	yz-component of total stress tensor applied at boundary faces
	szz	zz-component of total stress tensor applied at boundary faces
FIX	**x**	x-velocity fixed at boundary gridpoints
	y	y-velocity fixed at boundary gridpoints
	z	z-velocity fixed at boundary gridpoints

NOTE:

1. The **FREE** command is used to release the constraint set by the **FIX** command.
2. In order to assign a fixed-displacement boundary condition, only the **FIX x**, **FIX y** and/or **FIX z** commands are needed, provided that the velocity at the selected gridpoint is zero.
3. See Section 1 in the **Command Reference** for a complete listing of **APPLY** keywords.
4. Compressive stresses have a negative sign; see Section 2.8 for sign conventions.

Table 2.4 Summary of common initial condition commands

COMMAND		EFFECT
		Gridpoint Condition:
INITIAL	**xdis**	initialize x-displacement at a gridpoint
	xvel	initialize x-velocity at a gridpoint
	ydis	initialize y-displacement at a gridpoint
	yvel	initialize y-velocity at a gridpoint
	zdis	initialize z-displacement at a gridpoint
	zvel	initialize z-velocity at a gridpoint
		Zone Condition:
	density	initialize mass density for a zone
	sxx	initialize xx-component of total stress for a zone
	sxy	initialize xy-component of total stress for a zone
	sxz	initialize xz-component of total stress for a zone
	syy	initialize yy-component of total stress for a zone
	syz	initialize yz-component of total stress for a zone
	szz	initialize zz-component of total stress for a zone

By default, the boundaries in *FLAC3D* are free of stress and are unconstrained. Forces or stresses may be applied to any boundary, or portion of a boundary, by means of the **APPLY** command. Individual components of the stress tensor are specified by the keywords listed in Table 2.3. For example, a constant, compressive xx-stress component of 10 MPa can be applied to a boundary located at x = 10 with the command

```
apply sxx -10e6 range x 9.9 10.1
```

Remember that compressive stresses are negative. The **range** keyword is used at the end of the command line to specify the range of action for the **APPLY** command. In this case, the boundary condition applies to any boundary faces that fall between x = 9.9 and 10.1.

A linearly varying yy-stress component can be applied with the **gradient** keyword — for example,

```
apply syy = -20e6 grad 0,0,20e5 range y -20.1,-19.9 z 0,10
```

With this command, a yy-stress component is applied to boundary faces located between $y = -20.1$ and -19.9. The yy-stress varies linearly with z from $\sigma_{yy} = 0$ at $z = 10$, to $\sigma_{yy} = -20 \times 10^6$ at $z = 0$.

When **gradient** is used, a value varies according to the relation

$$S = S^{(o)} + g_x x + g_y y + g_z z \tag{2.5}$$

in which $S^{(o)}$ is the value at the global coordinate origin at (x = 0, y = 0, z = 0) and is the value immediately following the **syy** keyword, and g_x, g_y and g_z specify the variation of the value in the x-, y- and z-directions and are the three numbers following the **gradient** keyword.

Displacements cannot be controlled directly in *FLAC3D*. In fact, they play no part in the calculation process. In order to apply a given displacement to a boundary, it is necessary to prescribe the boundary's velocity for a given number of steps. If the desired displacement is D, a velocity V over N steps (where $N = D/V$) may be applied.* In practice, V should be kept small, and N large, in order to minimize shocks to the system being modeled. The **APPLY** command or the **FIX** and **INITIAL** commands can be used to specify the velocities; gradients may also be specified.

The following command shows the use of the **FIX** command to fix the x-displacement to zero along a boundary located at x = 0:

```
fix x range x -0.1 0.1
```

This, in effect, creates a roller boundary at which the boundary plane is fixed in the x-direction, but free to move in the y- and z-directions. Only the **FIX** command is needed if the model is at the start-up state and velocities are (by default) zero. Otherwise it would be necessary to either initialize velocities with the **INITIAL** command, or use the **APPLY** command.

A pinned boundary condition (i.e., constrained in the x-, y- and z-directions) can be specified with the command

```
fix x y z  range x -0.1 0.1
```

For real boundaries, the choice of stress or displacement boundary conditions is usually clear. However, for artificial boundaries, such as planes of truncation, either type may be selected. Experience has shown that, generally:

(1) a fixed boundary causes both stresses and displacements to be underestimated;

(2) a stress boundary causes both stresses and displacements to be overestimated; and

(3) the two types of boundary conditions bracket the true solution, so that it is possible to do tests with both boundaries and get a reasonable estimate of the true solution by averaging the two results.

Unlike the boundary condition commands, the initial condition commands assign *initial* values to selected variables; these *can* change while the computation proceeds. For example, in geological

---

* Note that velocity has units of *displacement per timestep* for the static solution mode, and *displacement per unit time* for the dynamic mode.

materials, there is an in-situ state of stress in the ground before any excavation or construction is started. By setting the initial conditions in a *FLAC3D* grid, an attempt to reproduce this in-situ state is made because it will influence the subsequent behavior of the model. (This influence is discussed in more detail in Section 3.3.)

To prescribe an initial stress state, we use the **INITIAL** command — e.g.,

```
ini sxx -50e6 syy -40e6 szz -10e6
```

This assigns initial compressive stress components of

σ_{xx} = -50e6
σ_{yy} = -40e6
σ_{zz} = -10e6

to all zones in the model. All six stress components can be initialized, and a stress gradient can be specified for boundary stresses in the same manner as previously discussed.

If the initial stress state is subjected to gravitational loading, this may be added via the **SET gravity** command — e.g.,

```
set gravity = 0, -9.81, 0
```

in which a gravitational acceleration vector of 9.81 m/sec^2 is applied in the negative y-direction. If gravitational loading is specified, the material mass density must also be initialized with the command **INI density**.

Let us now apply the information we have covered thus far to revise the trench model presented in Section 2.2. We can identify two planes of symmetry for this problem: one is the xy-plane; and the other is the yz-plane through the center of the trench (see Figure 2.12). The following commands (in Example 2.20) create the quarter-symmetry model, assign a Mohr-Coulomb material model and properties, prescribe boundary conditions, and apply the initial stress state with gravity acting in the positive y-direction. The model is shown in Figure 2.14.

In this example, σ_{xx} and σ_{zz} stresses and gradients are equal to half the σ_{yy} stresses and gradients. Stresses may be initialized to any value, but you must check the stress state to ensure that it does not violate the yield criterion (Mohr-Coulomb, in this case). The initial equilibrium state is discussed further in the next section.

Example 2.20 Trench problem — quarter-symmetry model

```

2.7.4 Stepping to Initial Equilibrium

The *FLAC3D* model must be at an initial force-equilibrium state before alterations can be performed. For simple model geometries, the boundary conditions and initial conditions may be assigned such that the model is exactly at equilibrium initially. However, in most cases, it is necessary to step the model to the initial equilibrium state under the given boundary and initial conditions, particularly for problems with complex geometries or multiple materials. This is done using either the **STEP** or **SOLVE** command. With the **STEP** command, the user specifies a number of calculation steps to perform in order to bring the model to equilibrium. The model is in perfect equilibrium when the net nodal-force vector at each gridpoint is zero (see Section 1 in **Theory and Background**). The maximum nodal-force vector (called the maximum "out-of-balance" or "unbalanced" force) is

monitored in *FLAC3D* and printed to the screen when the **STEP** command is invoked. In this way, the user can assess when equilibrium has been reached.

For a numerical analysis, the out-of-balance force will never reach exactly zero. It is sufficient, though, to say the model is in equilibrium when the maximum unbalanced force is small compared to the representative zone forces in the problem. For example, if the maximum unbalanced force is initially 1 MN and drops to approximately 100 N, then the model can be considered to be at equilibrium, within 0.01% of the initial maximum unbalanced force.

This is an important aspect of numerical problem-solving with *FLAC3D*. The user must decide when the model has reached equilibrium. There are several features built into *FLAC3D* to assist in making this decision. The history of the maximum unbalanced force may be recorded with the command

```
hist unbal
```

Additionally, the history of selected variables (e.g., velocity or displacement at a gridpoint) may be recorded. The following commands are examples.

```
hist gp xvel 5,4,4
hist gp zdisp 0,0,8
```

This first history records x-velocity at location (x = 5, y = 4, z = 4), while the second records z-displacement at location (x = 0, y = 0, z = 8).

After running several hundred (or thousand) calculation steps, a history of these records may be plotted to indicate the equilibrium condition. The data file in Example 2.21 illustrates this process.

Example 2.21 Stepping to initial equilibrium

```
gen zone brick size 6 8 8
mo elas
prop bulk 1e8 shear 0.3e8
fix x range x -0.1 0.1
fix x range x  5.9 6.1
fix y range y -0.1 0.1
fix y range y  7.9 8.1
fix z range z -0.1 0.1
apply szz -1e6 range z 7.9 8.1
hist unbal
hist gp xvel 3 4 4
hist gp zdisp 0 0 8
step 1500
; solve
```

The initial maximum unbalanced force is 1 MN. After 1500 steps, this force has dropped to approximately 270 N. By plotting the first history, it can be seen that the maximum unbalanced force is approaching zero. The following command produces the plot in Figure 2.15.

```
plot hist 1
```

The velocity also approaches zero, and the displacement history becomes constant; these are indicators that an equilibrium state is reached. The x-velocity history plot in Figure 2.16 and z-displacement history plot in Figure 2.17 are produced with the commands

```
plot hist 2
plot hist 3
```

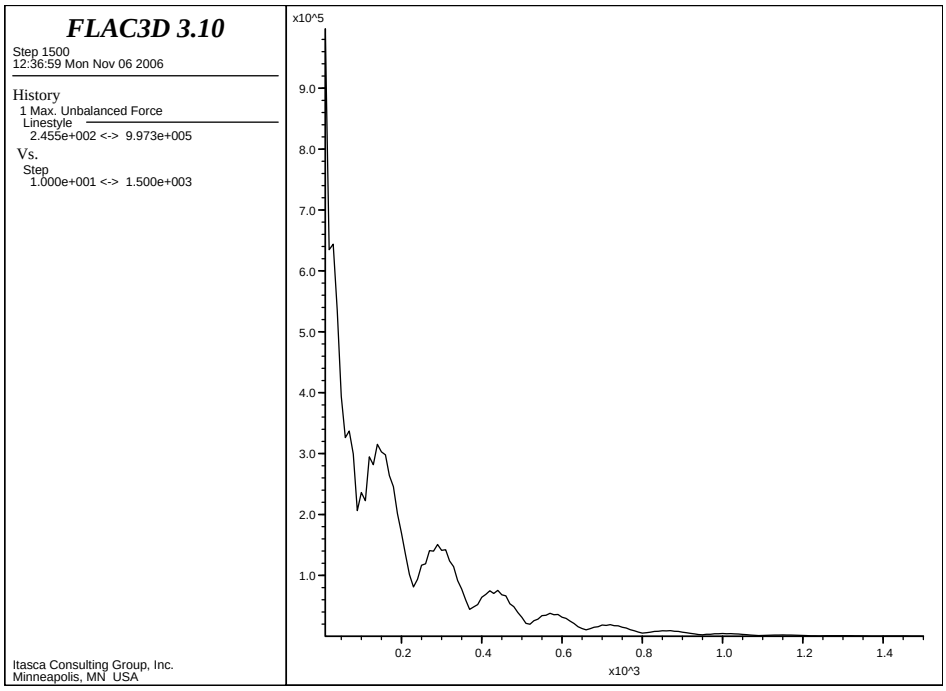

Figure 2.15 Maximum unbalanced force history

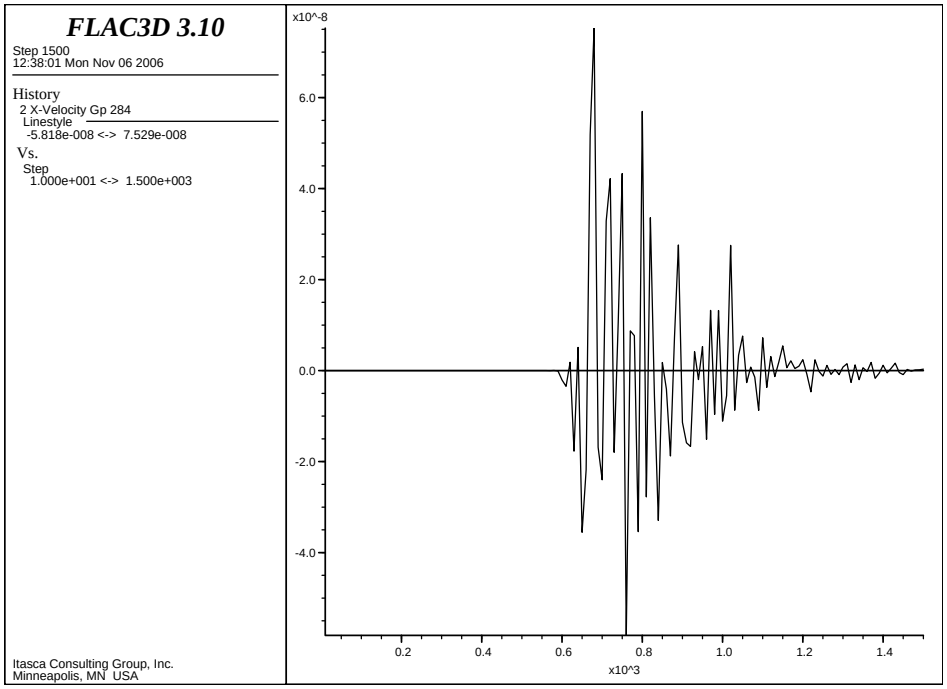

Figure 2.16 x-velocity history at (x = 3, y = 4, z = 4)

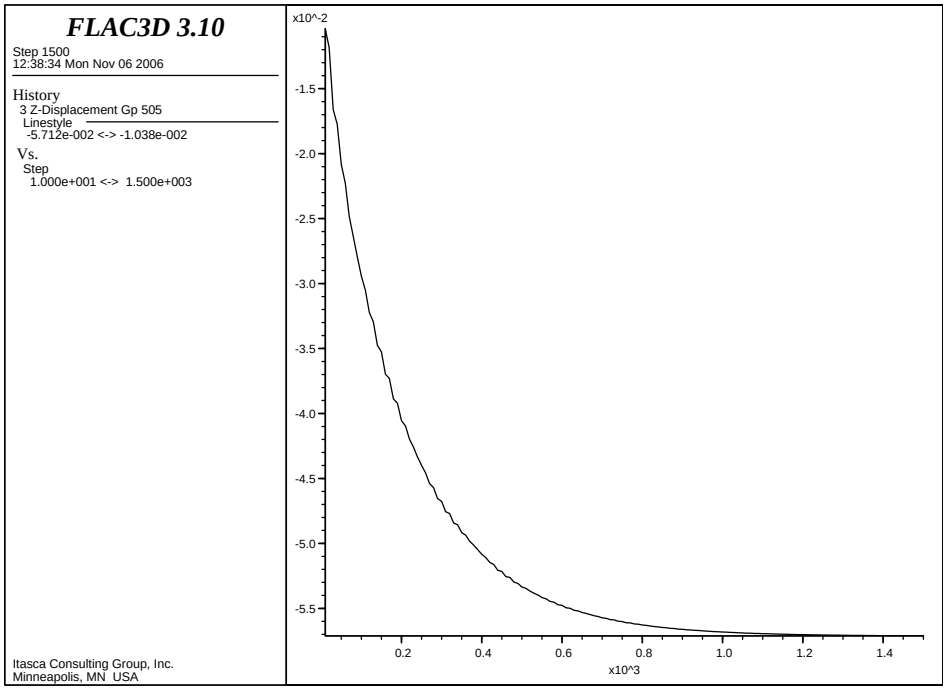

Figure 2.17 z-displacement history at (x = 0, y = 0, z = 8)

The **SOLVE** command can be used in place of **STEP** if the user wishes *FLAC3D* to stop automatically when the maximum unbalanced force falls below a specified limit. Replace **STEP 1500** with **SOLVE** and repeat the preceding problem. This time, *FLAC3D* should stop the calculation at step 1650. If the plots are made again, essentially the same results as given in Figures 2.15, 2.16 and 2.17 will be seen.

By default, a force-limit ratio controls the stepping when **SOLVE** is issued. When the ratio of the maximum unbalanced force for all the gridpoints in the model divided by the average applied gridpoint force falls below the value of 1.0×10^{-5}, then the calculation will stop. The ratio can be changed by typing

```
set mech ratio = f
```

before giving the **SOLVE** command. Here *f* is a user-supplied value for the force-limit ratio.

For Example 2.21, the initial equilibrium stage can be achieved without stepping by simply inserting an **INITIAL** command,

```
ini sxx=-1e6 syy=-1e6 szz=-1e6
```

Now, the unbalanced force is nearly zero.* Type **SOLVE** to confirm this. Note that, in this case, the initial displacements in the model are automatically zero.

If we return to the trench problem, the model described by the data file (Example 2.20) should be at a stress equilibrium state. After entering the data file, type

```
step 1
```

and you will find that the unbalanced force is approximately 7000 N. This is small relative to the maximum gravitational force for this problem (approximately 2.7×10^5 N). There is some force unbalance, however, because of the graded mesh. If the zones were all of equal size, the unbalanced force would be nearly zero. However, with graded meshes, it is usually necessary to perform some stepping to bring the model to an initial equilibrium state. Type

```
solve
```

and Example 2.20 will step to equilibrium, at an unbalanced force ratio limit of 1×10^{-5}, within 1040 steps.

In an analysis, it is very important that the model be at equilibrium before alterations are made. Several histories should be recorded throughout a model to ensure that a large force imbalance does not exist. It does not adversely affect the analysis if more steps are taken than are needed to reach equilibrium. However, it will affect the analysis if an insufficient number of steps is taken.

A *FLAC3D* calculation can be interrupted at any time during stepping by pressing the <Esc> key. It often is convenient to use the **STEP** command with a high step-number and periodically interrupt the stepping, check the histories, and resume stepping until the equilibrium condition is reached.

---

* The force is not exactly zero because of the difference between single- and double-precision calculations made in the code.

2.7.5 Performing Alterations

FLAC3D allows model conditions to be changed at any point in the solution process. These changes may take the following forms:

- excavation of material;
- addition or deletion of gridpoint loads or stresses;
- change of material model or properties for any zone; and
- fix or free velocities for any gridpoint.

Excavation is performed with the **MODEL null** command. Gridpoint loads can be applied at any gridpoint with the **APPLY xforce**, **APPLY yforce** and **APPLY zforce** commands. Stress alterations can be made at model boundaries with the **APPLY** command, as discussed previously. Material models and properties* are changed with the **MODEL** and **PROPERTY** commands. Gridpoint velocities are fixed or freed via the **FIX**/**FREE** commands. It should be evident that several commands can be repeated to perform various model alterations.

If model zones contain a plasticity model (e.g., **MODEL mohr**), it is possible that an alteration may be such that force equilibrium cannot be achieved. In other words, the unbalanced forces in part or all of the model cannot approach zero — in which case, the maximum unbalanced force will approach a constant nonzero value, indicating that steady-state flow of material is occurring (i.e., a portion (or all) of the model is failing).

In our trench model, Example 2.20, we define and excavate the trench and monitor the response with the commands in Example 2.22.

Example 2.22 Excavating the trench and monitoring the response

```
range name trench x=0,1  y=0,4  z=0,2
model null range trench
set large
hist gp xdisp 1,0,0
; ... and then calculate the response:
step 1000
```

The trench fails as indicated by the plot in Figure 2.18. The displacement history at the trench wall, Figure 2.19, also indicates failure by a continuously increasing displacement.

---

* If moduli (bulk or shear) are changed in a model that is in equilibrium, no immediate effect will be observed because *FLAC3D* uses *tangent*, rather than *secant*, moduli.

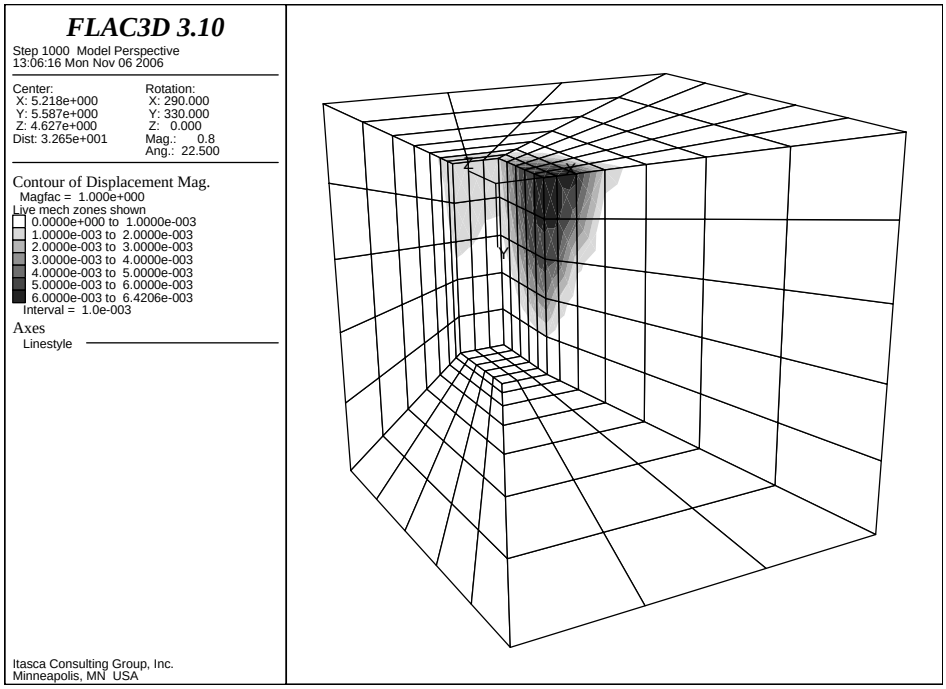

Figure 2.18 Displacement contours for trench excavation

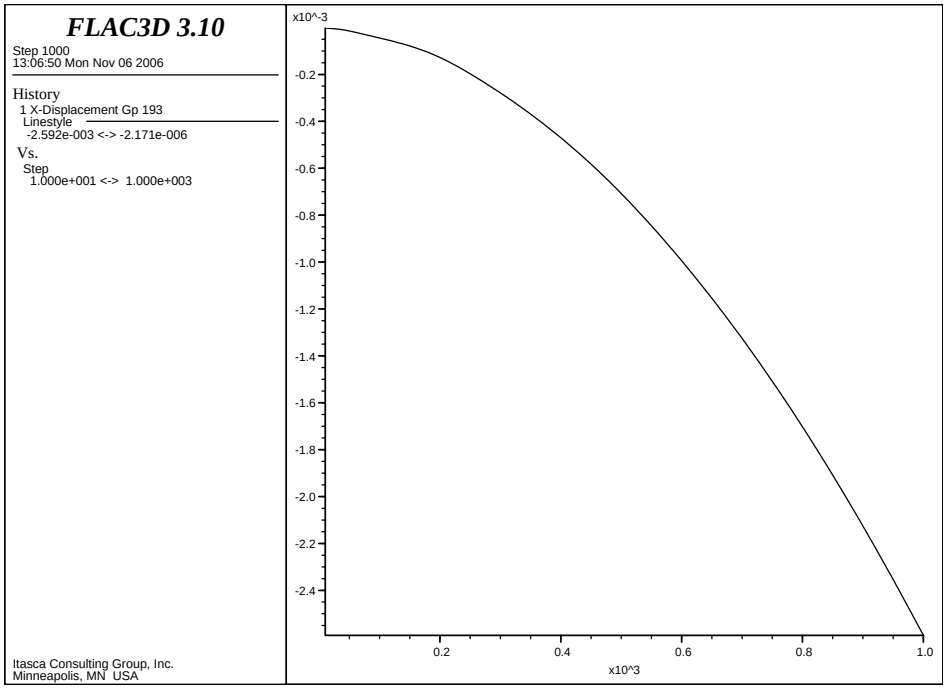

Figure 2.19 Displacement history at trench wall

2.7.6 Saving/Restoring the Problem State

Two other commands, **SAVE** and **RESTORE**, are helpful when performing analyses in stages (also available under the FILE menu). At the end of one stage (e.g., initial equilibrium), the model state can be saved (as a binary file) by typing

```
save file.sav
```

in which file is a user-specified filename. The (default) extension ".SAV" identifies this file as a saved file (see Section 2.11). This file can be restored at a later time by typing

```
rest file.sav
```

and the model state at the point at which the model was saved will be restored. It is not necessary to build a model from scratch every time a change is made; simply save the model before the change, and restore it whenever a new change is to be analyzed.

For example, in our trench problem we will excavate the trench in 2 m-deep stages and save the state at each stage, beginning with the initial equilibrium stage ("TR_EQ.SAV"). We can then determine the stage at which the trench fails and investigate the influence of support (e.g., tiebacks or soil nails) on stabilizing the trench.

We repeat the data file given in Example 2.20, but this time we insert save files at the equilibrium stage and at each excavation stage.

Upon running this example, we find that the trench fails at the third excavation stage (see the x- and z-displacement history plot in Figure 2.20). We restart the save file at the second excavation stage ("EXC2.SAV"), install cables and then proceed with the excavation. (See the **SEL cable** command in Section 1 in the **Command Reference**.) This time, the trench walls are stable (see Figure 2.21). The forces in the cables and displacements of the trench are shown in Figure 2.22.

By using save files, we can perform series of different calculations, starting from whatever stage we desire, and investigate various problem conditions such as spacing and properties of cable elements.

2.7.7 Summary of Commands for Simple Analysis

The major command words described in Section 2.7 are summarized in Table 2.5. This table also illustrates the recommended command sequence for creating and running a model. These commands are all that are needed to begin performing simple analyses with *FLAC3D*. Start by running simple tests with these commands (e.g., uniaxial and confined compression tests or simple excavation-stability analyses). It may be helpful to review the detailed description of these commands in Section 1 in the **Command Reference**. Then try adding more complexity to the model. Before attempting very detailed simulations, we recommend that you read Section 3.3, which provides guidance on problem solving in general.

Table 2.5 Basic commands for simple analyses

FUNCTION	COMMAND
Grid generator	**GEN**
Material model and properties	**MODEL** **PROPERTY**
Boundary/initial conditions	**APPLY** **FIX** **INITIAL**
(with gravity)	**SET gravity**
Initial equilibrium	**STEP** **SOLVE**
Perform alterations	**MODEL** **PROPERTY** **APPLY** **FIX** **FREE**
(with support)	**SEL cable**
Save/restore problem state	**SAVE** **RESTORE**

2.8 Sign Conventions

The following sign conventions are used in *FLAC3D*, and must be kept in mind when entering input or evaluating results.

DIRECT STRESS — Positive stresses indicate tension; negative stresses indicate compression.

SHEAR STRESS — With reference to Figure 2.23, a positive shear stress points in the positive direction of the coordinate axis of the second subscript if it acts on a surface with an outward normal in the positive direction. Conversely, if the outward normal of the surface is in the negative direction, then the positive shear stress points in the negative direction of the coordinate axis of the second subscript. The shear stresses shown in Figure 2.23 are all positive. The stress tensor is symmetric — i.e., complementary shear stresses are equal.

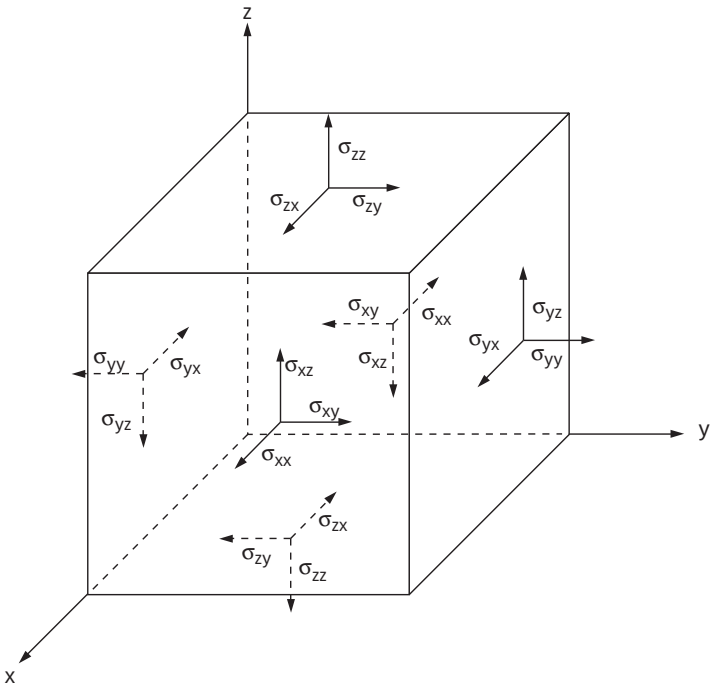

Figure 2.23 Sign convention for positive stress-components

DIRECT STRAIN — Positive strain indicates extension; negative strain indicates compression.

SHEAR STRAIN — Shear strain follows the convention of shear stress (see above).

PRESSURE — A positive pressure will act normal to, and in a direction toward, the surface of a body (i.e., push). A negative pressure will act normal to, and in a direction away from, the surface of a body (i.e., pull). Figure 2.24 illustrates this convention.

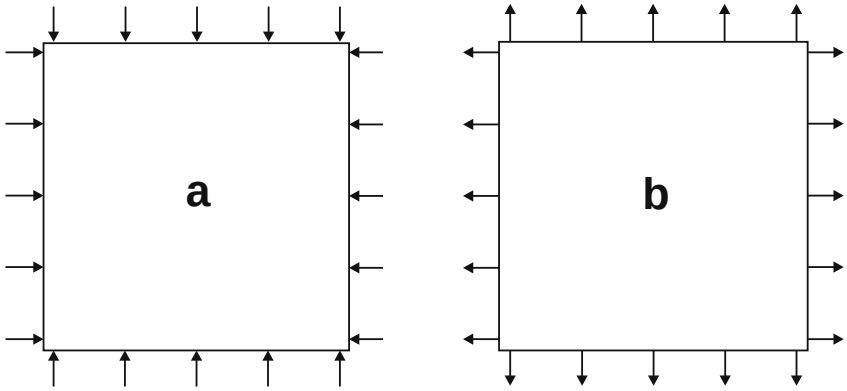

Figure 2.24 Mechanical pressure: (a) positive; (b) negative

PORE PRESSURE — Fluid pore pressure is positive in compression. Negative pore pressure indicates fluid tension.

DIP, DIP DIRECTION — Dip and dip direction assume that the x-direction corresponds to "East," the y-direction to "North," and the z-direction to "Up." The dip angle is measured in the negative z-direction from the global xy-plane. The dip direction angle is measured in the global xy-plane, clockwise from the positive y-axis. The x-, y- and z-components of vector quantities, such as forces, displacements and velocities, are positive when pointing in the directions of the positive x-, y- and z-coordinate space.

2.9 Systems of Units

FLAC3D accepts any consistent set of engineering units. Examples of consistent sets of units for basic parameters are shown in Tables 2.6 and 2.7. The user should apply great care when converting from one system of units to another. An excellent reference on the subject of units and conversion between the Imperial and SI systems can be found in the *Journal of Petroleum Technology* (December 1977). No conversions except for friction and dilation angles, which are entered in degrees, are performed in *FLAC3D*.

Table 2.6 Systems of units — mechanical parameters

	SI				Imperial	
Length	m	m	m	cm	ft	in
Density	kg/m^3	10^3 kg/m^3	10^6 kg/m^3	10^6 g/cm^3	slugs/ft^3	snails/in^3
Force	N	kN	MN	Mdynes	lb_f	lb_f
Stress	Pa	kPa	MPa	bar	lb_f/ft^2	psi
Gravity	m/sec^2	m/sec^2	m/sec^2	cm/s^2	ft/sec^2	in/sec^2

where 1 bar = 10^6 dynes/cm^2 = 10^5 N/m^2 = 10^5 Pa;
1 atm = 1.013 bars = 14.7 psi = 2116 lb_f/ft^2 = 1.01325 × 10^5 Pa;
1 slug = 1 lb_f - s^2/ft = 14.59 kg;
1 snail = 1 lb_f -s^2/in; and
1 gravity = 9.81 m/s^2 = 981 cm/s^2 = 32.17 ft/s^2.

Table 2.7 Systems of units — groundwater flow parameters

	SI		Imperial	
Water bulk modulus	Pa	bar	lbf/ft^2	psi
Water density	kg/m^3	10^6 g/cm^3	slugs/ft^3	snails/in^3
Permeability	m^{3}sec/kg	10^{-6} cm sec/g	ft^3 sec/slug	in^3 sec/snail
Intrinsic permeability	m^2	cm^2	ft^2	in^2
Hydraulic conductivity	m/sec	cm/sec	ft/sec	in/sec

NOTE: *FLAC3D* permeability (in SI units) ≡ intrinsic permeability (in cm^2) × 9.9 × 10^{-2}
≡ hydraulic conductivity (in cm/sec) × 1.02 × 10^{-6}

FLAC3D permeability is the *mobility coefficient* (coefficient of pore pressure term in Darcy's law).

Systems of units for parameters associated with structural elements and heat transfer are given in Section 1 in **Structural Elements** and Section 1 in **Optional Features**, respectively.

2.10 Precision Limits

When selecting a system of units, care should be taken to avoid calculations that approach the precision limits of the computer hardware. For 80386/387-based computers, the range is approximately 10^{-300} to 10^{300} in double-precision. If numbers exceed these limits, it is likely that the program will crash, or at least produce artifacts in the model that may be difficult to identify or detect.

2.11 Files

There are six types of files that are either used or created by *FLAC3D*. The files are distinguished by their extensions and are described below.

INITIALIZATION FILE

"FLAC3D.INI" — This is a formatted ASCII file, created by the user, that *FLAC3D* will automatically access upon start-up or when a **NEW** command is issued. *FLAC3D* searches for the file "FLAC3D.INI" in the directory in which the code is executed and, if not found, in the directory pointed to by the ITASCA environment variable. The file may contain any valid *FLAC3D* command(s) (see Section 1 in the **Command Reference**). Although this file does not need to exist (i.e., no errors will result if it is absent), it is normally used to change default options in *FLAC3D* to those preferred by the individual user each time a new analysis is run (see Section 2.1.7).

DATA FILES

The user has a choice of running *FLAC3D* interactively (i.e., entering *FLAC3D* commands while in the *FLAC3D* environment) or via a data file (also called a "batch file"). The data file is a formatted ASCII file created by the user which contains the set of *FLAC3D* commands that represents the problem being analyzed. In general, creating data files is the most efficient way to use *FLAC3D*. To use data files with *FLAC3D*, see the **CALL** command in Section 1 in the **Command Reference**. Data files can have any filename and any extension. It is recommended that a common extension (e.g., ".DAT" for *FLAC3D* input commands, and ".FIS" for *FISH* function statements) be used to distinguish these files from other types of files.

SAVE FILES

"FLAC3D.SAV" — This file is created by *FLAC3D* at the user's request when issuing the command **SAVE**. The default file name is "FLAC3D.SAV," which will appear in the default directory when quitting *FLAC3D*. The user may specify a different file name by issuing the command **SAVE** filename, where filename is a user-specified file name. "FLAC3D.SAV" is a binary file containing the values of all state variables and user-defined conditions. The primary reason for creating save files is to allow one to investigate the effect of parameter variations without having to rerun a problem completely. A save file can be restored and the analysis continued at a subsequent time (see the **RESTORE** command in Section 1 in the **Command Reference**). Normally, it is good practice to create several save files during a *FLAC3D* run.

LOG FILES

"FLAC3D.LOG" — This file is created by *FLAC3D* at the user's request when issuing the command **SET log on**. It is a formatted ASCII file. The default name of the file is "FLAC3D.LOG," which will appear in the default directory after quitting *FLAC3D*. The user may specify a different file name by issuing the command **SET logfile** filename, where filename is a user-supplied file name. The command may be issued interactively or be part of a data file. Subsequent to the **SET log on** command, all text appearing on the screen will be copied to the log file. The log file is useful in

providing a record of the *FLAC3D* work session; it also provides a document for quality-assurance purposes.

HISTORY FILES

"FLAC3D.HIS" — This file is created by *FLAC3D* at the user's request when issuing the command **HISTORY write *n***, where ***n*** is a history number (see the **HISTORY** command, Section 1 in the **Command Reference**). It is a formatted ASCII file. The default name of the file is "FLAC3D.HIS," which will appear in the default directory after quitting *FLAC3D*. The user may specify a different file name by issuing the keyword phrase **file** myfile.his at the end of the **HISTORY write** command.

The command may be issued interactively or be part of a data file. A record of the history values is written to the file, which can be examined using any text editor that can access formatted ASCII files. Alternatively, the file may be processed by a commercial graph-plotting or spreadsheet package.

PLOT FILES

Plot files are created at the user's request by issuing the command **PLOT hardcopy** in the command mode, or by pressing the FILE PRINT menu item from the main *FLAC3D* window. In both cases, a plot will be directed to the current Windows printer. The user may specify a plot file name by giving the command **SET output** myfile.ps, where "MYFILE.PS" is a user-specified filename. Other graphics output options are described in Section 2.1.4.

MOVIE FILES

DCX Movie — This file is created by *FLAC3D* at the user's request when issuing the commands **SET movie dcx** and **MOVIE**. Its purpose is to capture graphics images for playback as a movie using the movie utility supplied with the Itasca software product ("MOVIE.EXE," located in "c:\Program Files\Itasca\Shared\Utility). The default file name is "FLAC3D.DCX," which will appear in the default directory when quitting *FLAC3D*. The user may specify a different file name by issuing the command **SET movie file** filename, where filename takes the place of "FLAC3D.DCX." A DCX file format is used for the movie file when **SET movie dcx** is specified. DCX files are a collection of PCX files and include an index to the PCX files. A DCX file can contain up to 1024 PCX images. See the **MOVIE** and **SET movie** commands in Section 1 in the **Command Reference**.

AVI Movie — This file is created by *FLAC3D* at the user's request when issuing the commands **SET movie avi** and **MOVIE**. Its purpose is to capture graphics images for playback as a movie using the standard Windows Media Player. The default file name is "FLAC3D.AVI," which will appear in the default directory when quitting *FLAC3D*. The user may specify a different file name by issuing the command **SET movie file** filename, where filename takes the place of "FLAC3D.AVI." The AVI file format is used for the movie file when **SET movie avi** is specified. See the **MOVIE** and **SET movie** commands in Section 1 in the **Command Reference**.

FISH I/O FILES

A user-written *FISH* function may create, write and read files (see Section 2.7.2 in the ***FISH* volume**) of two forms. If the binary form is selected, the exact binary representation of a *FISH*

variable is stored on file. If the ASCII form is selected, numeric or character data may be written, or read from, a file. The latter form is a useful way to process ASCII data in a non-standard way on file.

2.12 Introducing the *FLAC3D* Graphical User Interface

This section is intended to provide a brief introduction to the use of the *FLAC3D* Graphical User Interface, or GUI. The primary uses of the GUI at this time are in accessing the powerful plotting functions in *FLAC3D*, and in file handling. The GUI allows the user to switch directly from keyboard (command-line) control to mouse control of *FLAC3D*. It is assumed that a mouse is attached to the computer, and that both the hardware and software components of the mouse are working correctly.

When *FLAC3D* is loaded, the main *FLAC3D* window will appear (Figure 2.25). The code name and current version number are printed in the title bar at the top of the window, and a menu bar is positioned just below the title bar. A bar with the `Flac3D>` prompt is in a command line window located at the bottom of the main window; any *FLAC3D* commands can be entered here. The command window echoes all the input to, and output from, *FLAC3D*. Moving the mouse should result in the cursor moving around the main window; various components should become highlighted as the mouse pointer moves over them and the mouse button is clicked.

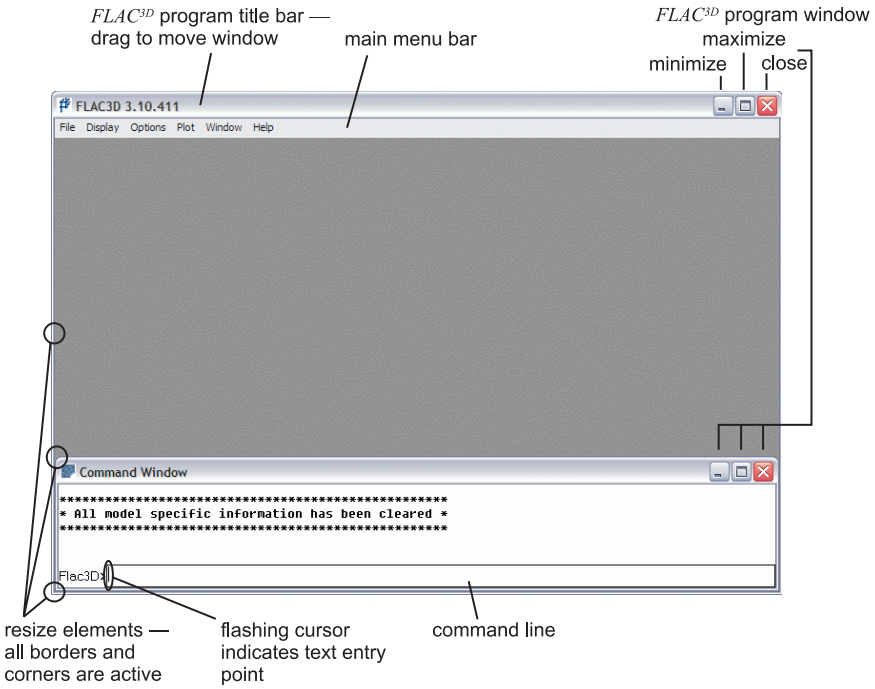

Figure 2.25 The FLAC3D main window

The underlined letters on the menu items represent hot-keys — press <ALT-*key*> to activate a main menu item. Once a main menu item is selected and its drop-down menu appears, as in Figure 2.26, that drop-down menu has the keyboard focus. Pressing the hot-key for any item on the drop-down menu on its own (i.e., without pressing <ALT>) will select that item. This is true for all of the drop-down menus. Pressing <Esc> clears the menu.

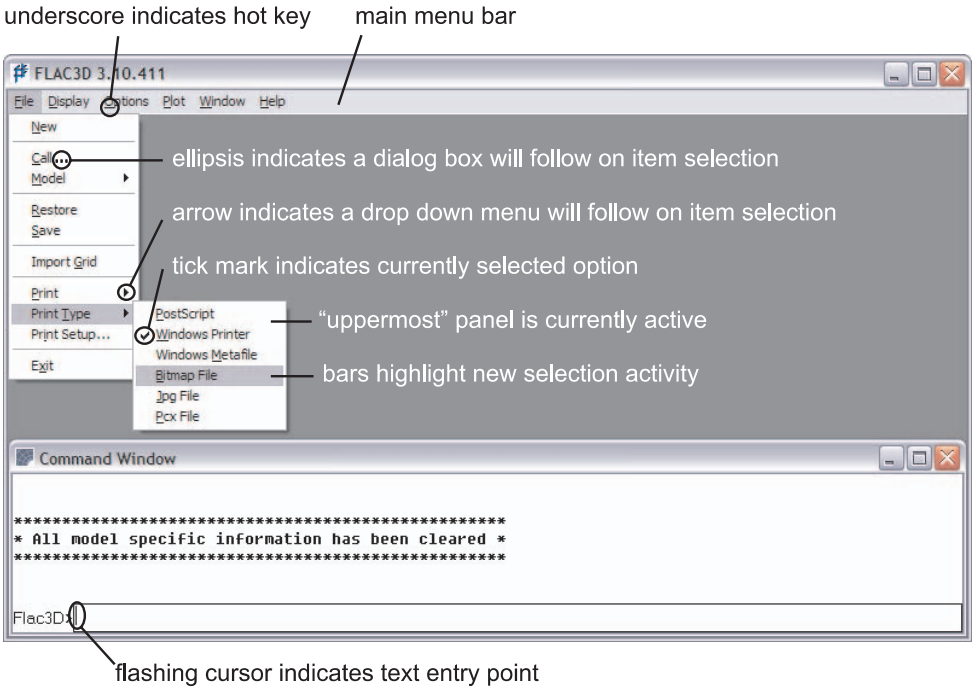

Figure 2.26 The menu items

From the freshly started main window, try pressing

```
Alt-F
C
```

to get the dialog box enabling the selection of a data file. Single clicks with the mouse on the FILE and then the CALL menu options will produce the same result. Your screen should display a dialog box similar to that shown in Figure 2.27.

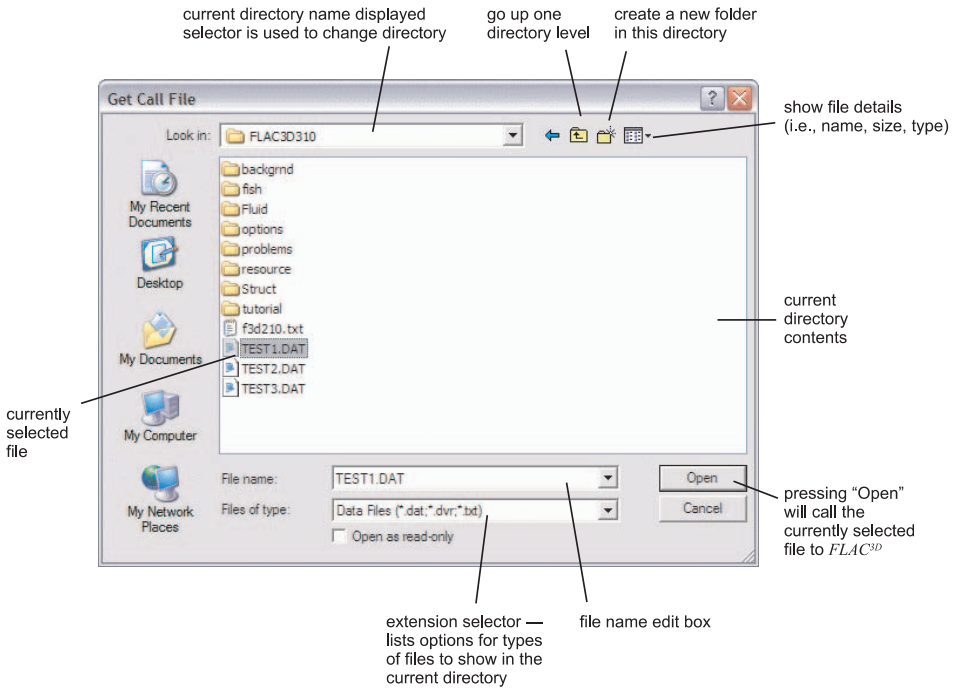

Figure 2.27 The FILE/CALL dialog box

Looking at the FILE/CALL dialog box, we see a list box containing files and sub-directories within the *FLAC3D* directory. With the mouse, clicking on a list name will either open the sub-directory or cause the file to be chosen for calling into *FLAC3D*. For example, we wish to open the data file "TRENCH1.DAT" that is located in the "\Tutorial\Beginner" directory. Double-click on the "Tutorial" directory name in the list box, and then double-click on the "Beginner" directory name. Pick the file "TRENCH1.DAT" from the list; then click on the OPEN button to process the data file.

Pressing <ESC> will remove the dialog box from the screen. The <TAB> key will move the cursor between the edit fields.

The data file is opened and read, just as if we were entering the file with the **CALL** command. We can view a plot of our model while the model itself is still under construction. As any change that affects the current plot is made to the model, the plot is updated. Run the example and watch for the prompts at the bottom of the screen. Figure 2.28 shows the results at one particular position in the run.

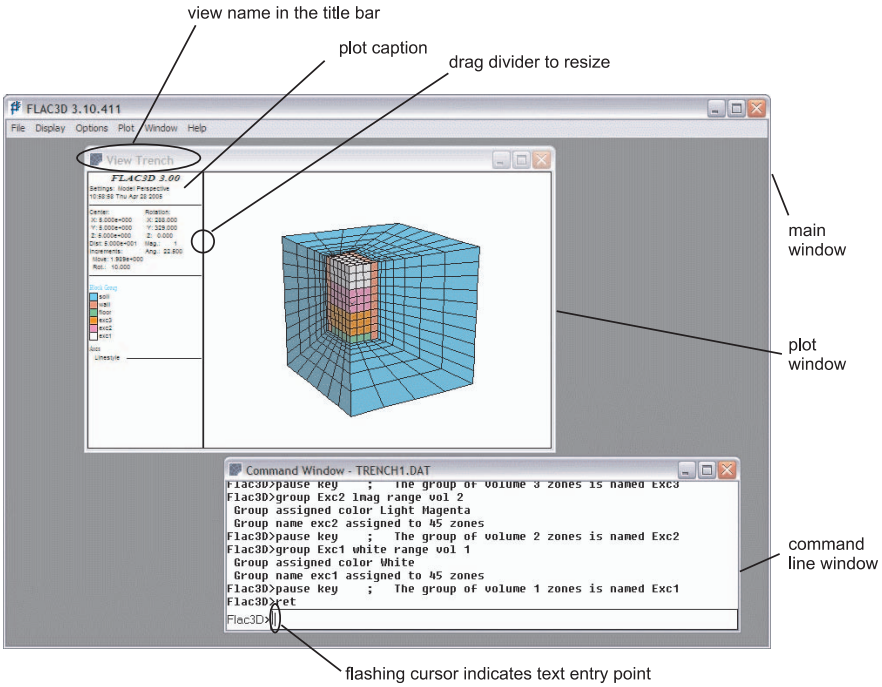

Figure 2.28 A plot window

We are simply examining the construction sequence in our model to see that we have things working in the right order. A tiny error during the copying of lines in the data file creation has corrupted the excavation sequence. To correct it, open the file "TRENCH1.DAT" in your favorite editor, change the comment symbols as shown in Example 2.24, and save the edited file.

Example 2.24 Using comments during model testing

```
change this ...
     model null range region Exc1    ;swap the comment marker at the
     ;model null range region Exc2   ;start of these two lines

to look like this ...
     ;model null range region Exc1   ;swap the comment marker at the
     model null range region Exc2    ;start of these two lines
```

Call "TRENCH1.DAT" again to see whether the excavation now works.

Clicking the mouse button on a plot window will open the plot menu for that view. The plot menu bar replaces the main menu bar below the title bar. Moving the mouse pointer over a selectable button in the plot menu and clicking the mouse causes a drop-down menu to open. For example, by clicking on PLOTITEMS in the plot menu, a menu will open with options to add or modify plot items on the active plot view.

The interactive plotting control keys are available to a plot window that has focus. Try pressing the <M> key — one of two things will happen: if the plot window has focus, the plot image will be magnified; if the command window has focus, an "m" will appear on the command line. A mouse click on an area will pull the focus to that area. Pressing <ENTER> will shift the focus from a plot window to the command window.

Any *FLAC3D* command can be entered at the command line to modify the currently active plot. Click on the command line to give it focus and type

```
plot modi 1 range group Soil not
```

followed by the <ENTER> key. The current plot window is updated automatically every time a command that affects the view contained in that plot window is issued.

The preceding modification can also be made from the plot menu by clicking on the PLOTITEMS menu item, then the 1BLOCK GROUP menu item, and then the MODIFY menu item. This will open a *Block Group* dialog box. To remove a block group from the plot, click on the EDITRANGE button, and this will open a *Get Range* dialog box. The soil group can be removed from the plot by clicking on the ADD button, then double-clicking on the *Group* range element, clicking the *Soil* group, and finally clicking the NOT item. Click OK twice to view the change.

Example 2.25 contains a complete listing of "TRENCH1.DAT" as used in this tutorial.

3 PROBLEM SOLVING WITH *FLAC3D*

This section provides guidance in the use of *FLAC3D* in problem solving for static mechanical analysis* in geotechnical engineering. In Section 3.1, an outline of the steps recommended for performing a geomechanics analysis is given, followed in Sections 3.2 through 3.9 by an examination of specific aspects that must be considered in any model creation and solution. These include:

- grid generation (Section 3.2);
- boundary and initial conditions (Sections 3.3 and 3.4);
- loading and sequential modeling (Section 3.5);
- choice of constitutive model and material properties (Sections 3.6 and 3.7);
- ways to improve modeling efficiency (Section 3.8); and
- interpretation of results (Section 3.9).

Each of these modeling aspects is discussed in detail. The user who is familiar with the two-dimensional program *FLAC* will find that the modeling approach is very similar in *FLAC3D*. The major difference is the procedure for grid generation. We recommend that Section 3.2 be studied carefully, and that the example problems in that section be repeated before users create their own model grids. You will note that *FISH* programs are used in this section to assist with model generation and problem solving. If you have not used the *FISH* language before, we recommend that you first read the *FISH* tutorial in Section 4.2.

Finally, the philosophy of modeling in the field of geomechanics is examined in Section 3.10; the novice modeler in this field may wish to consult this section first. The methodology of modeling in geomechanics can be significantly different from that in other engineering fields, such as structural engineering. It is important to keep this in mind when performing any geomechanics analysis.

---

* Problem solving for coupled mechanical-groundwater analysis is discussed in Section 1 in **Fluid-Mechanical Interaction**, and for coupled mechanical-thermal analysis in Section 1 in **Optional Features**. Problem solving for dynamic analysis is discussed in Section 3 in **Optional Features**.

3.1 General Approach

The modeling of geo-engineering processes involves special considerations and a design philosophy different from that followed for design with fabricated materials. Analyses and designs for structures and excavations in or on rocks and soils must be achieved with relatively little site-specific data, and an awareness that deformability and strength properties may vary considerably. It is impossible to obtain complete field data at a rock or soil site. For example, information on stresses, properties and discontinuities can only be partially known, at best.

Since the input data necessary for design predictions is limited, a numerical model in geomechanics should be used primarily to understand the dominant mechanisms affecting the behavior of the system. Once the behavior of the system is understood, it is then appropriate to develop simple calculations for a design process.

This approach is oriented toward geotechnical engineering, in which there is invariably a lack of good data. But, in other applications, it may be possible to use *FLAC3D* directly in design if sufficient data, as well as an understanding of material behavior, is available. The results produced in a *FLAC3D* analysis will be accurate when the program is supplied with appropriate data. Modelers should recognize that there is a continuous spectrum of situations, as illustrated in Figure 3.1:

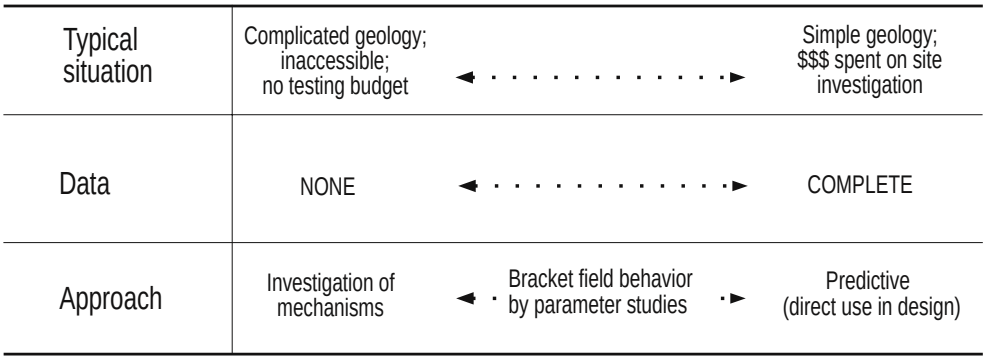

Figure 3.1 Spectrum of modeling situations

FLAC3D may be used either in a fully predictive mode (right-hand side of Figure 3.1) or as a "numerical laboratory" to test ideas (left-hand side). It is the field situation (and budget), rather than the program, that determines the types of use. If enough data of a high quality is available, *FLAC3D* can give good predictions.

Since most *FLAC3D* applications will be for situations in which little data is available, this section discusses the recommended approach for treating a numerical model as if it were a laboratory test. The model should never be considered as a "black box" that accepts data input at one end and produces a prediction of behavior at the other. The numerical "sample" must be prepared carefully, and several samples tested, to gain an understanding of the problem. Table 3.1 lists the steps recommended to perform a successful numerical experiment; each step is discussed separately.

Table 3.1 Recommended steps for numerical analysis in geomechanics

Step 1	Define the objectives for the model analysis
Step 2	Create a conceptual picture of the physical system
Step 3	Construct and run simple idealized models
Step 4	Assemble problem-specific data
Step 5	Prepare a series of detailed model runs
Step 6	Perform the model calculations
Step 7	Present results for interpretation

3.1.1 Step 1: Define the Objectives for the Model Analysis

The level of detail to be included in a model often depends on the purpose of the analysis. For example, if the objective is to decide between two conflicting mechanisms that are proposed to explain the behavior of a system, then a crude model may be constructed, provided that it allows the mechanisms to occur. It is tempting to include complexity in a model just because it exists in reality. However, complicating features should be omitted if they are likely to have little influence on the response of the model, or if they are irrelevant to the model's purpose. Start with a global view and add refinement as (and if) necessary.

3.1.2 Step 2: Create a Conceptual Picture of the Physical System

It is important to have a conceptual picture of the problem to provide an initial estimate of the expected behavior under the imposed conditions. Several questions should be asked when preparing this picture. For example, is it anticipated that the system could become unstable? Is the predominant mechanical response linear or nonlinear? Are movements expected to be large or small in comparison with the sizes of objects within the problem region? Are there well-defined discontinuities that may affect the behavior, or does the material behave essentially as a continuum? Is there an influence from groundwater interaction? Is the system bounded by physical structures, or do its boundaries extend to infinity? Is there any geometric symmetry in the physical structure of the system?

These considerations will dictate the gross characteristics of the numerical model, such as the design of the model geometry, the types of material models, the boundary conditions and the initial equilibrium state for the analysis. They will determine whether a three-dimensional model is required, or a two-dimensional model can be used to take advantage of geometric conditions in the physical system.

3.1.3 Step 3: Construct and Run Simple Idealized Models

When idealizing a physical system for numerical analysis, it is more efficient to construct and run simple test models first, before building the detailed model. Simple models should be created at the earliest possible stage in a project to generate both data and understanding. The results can provide further insight into the conceptual picture of the system; Step 2 may need to be repeated after simple models are run.

Simple models can reveal shortcomings that can be remedied before any significant effort is invested in the analysis. For example, do the selected material models sufficiently represent the expected behavior? Are the boundary conditions influencing the model response? The results from the simple models can also help guide the plan for data collection by identifying which parameters have the most influence on the analysis.

3.1.4 Step 4: Assemble Problem-Specific Data

The types of data required for a model analysis include:

- details of the geometry (e.g., profile of underground openings, surface topography, dam profile, rock/soil structure);
- locations of geologic structure (e.g., faults, bedding planes, joint sets);
- material behavior (e.g., elastic/plastic properties, post-failure behavior);
- initial conditions (e.g., in-situ state of stress, pore pressures, saturation); and
- external loading (e.g., explosive loading, pressurized cavern).

Since typically there are large uncertainties associated with specific conditions (in particular, state of stress, deformability and strength properties), a reasonable range of parameters must be selected for the investigation. The results from the simple model runs (in Step 3) can often prove helpful in determining this range, and in providing insight for the design of laboratory and field experiments to collect the needed data.

3.1.5 Step 5: Prepare a Series of Detailed Model Runs

Most often, the numerical analysis will involve a series of computer simulations that include the different mechanisms under investigation, and span the range of parameters derived from the assembled database. When preparing a set of model runs for calculation, several aspects, such as those listed below, should be considered.

1. How much time is required to perform each model calculation? It can be difficult to obtain sufficient information to arrive at a useful conclusion if model runtimes are excessive. Consideration should be given to performing parameter variations on multiple computers to shorten the total computation time.

2. The state of the model should be saved at several intermediate stages so that the entire run does not have to be repeated for each parameter variation. For example, if the analysis involves several loading/unloading stages, the user should be able to return to any stage, change a parameter and continue the analysis from that stage. The amount of disk space required for save files should be considered.

3. Are there a sufficient number of monitoring locations in the model to provide for a clear interpretation of model results and for comparison with physical data? It is helpful to locate several points in the model at which a record of the change of a parameter (such as displacement, velocity or stress) can be monitored during the calculation. Also, the maximum unbalanced force in the model should always be monitored to check the equilibrium or failure state at each stage of an analysis.

3.1.6 Step 6: Perform the Model Calculations

It is best to first make one or two model runs, split into separate sections, before launching a series of complete runs. The runs should be checked at each stage to ensure that the response is as expected. Once there is assurance that the model is performing correctly, several data files can be linked together to run a complete calculation sequence. At any time during a sequence of runs, it should be possible to interrupt the calculation, view the results, and then continue or modify the model as appropriate.

3.1.7 Step 7: Present Results for Interpretation

The final stage of problem solving is the presentation of the results for a clear interpretation of the analysis. This is best accomplished by displaying the results graphically, either directly on the computer screen or as output to a hardcopy plotting device. The graphical output should be presented in a format that can be directly compared to field measurements and observations. Plots should clearly identify regions of interest from the analysis, such as locations of calculated stress concentrations, or areas of stable movement versus unstable movement in the model. The numeric values of any variable in the model should also be readily available for more detailed interpretation by the modeler.

We recommend that these seven steps be followed to solve geo-engineering problems efficiently. The following sections describe the application of *FLAC3D* to meet the specific aspects of each of these steps in this modeling approach.

3.2 Grid Generation

At first, it may seem that the grid generation scheme in *FLAC3D* is limited to rather simple, regular-shaped regions; the examples given in Section 2.7 are all uniform, polyhedral grids. The *FLAC3D* grid, however, can be distorted to fit arbitrary and complicated volumetric regions. A powerful grid generator is built into *FLAC3D* to manipulate the grid to fit various shapes of three-dimensional problem domains.

The procedure for implementing the grid generator is described in this section. An overview of the generator operation is given first, in Section 3.2.1. This is followed, in Sections 3.2.2 and 3.2.3, by presentations on various aspects of grid generation, along with guidelines to follow in designing the grid for accurate solutions. Examples are given to illustrate each aspect. A special grid-generation tool is described in Section 3.2.4. This tool permits the generation of three-dimensional grids from two-dimensional (*FLAC*) data files by extruding the mesh in the third dimension.

One important aspect in grid generation is that all physical boundaries to be represented in the model simulation (including regions that will be added, or excavations created at a later stage in the simulation) *must* be defined before the solution stepping begins. Shapes of structures that will be added later in a sequential analysis must be defined and then removed (via **MODEL null**) until the appropriate time at which they are to be activated. The purpose of the grid generator is to facilitate the creation of all required physical shapes in the model.

3.2.1 Overview of the Grid Generator

Grid generation in *FLAC3D* involves patching together grid shapes of specific connectivity (referred to as *primitives*) to form a complete model with the desired geometry. Several types of primitives are available, and these can be connected and conformed to create complex three-dimensional geometries.*

Grid generation is invoked with the **GENERATE** command. The generation of zones for each primitive type is performed with the **GENERATE zone** command. Reference points can be defined with the **GENERATE point** command to assist with positioning gridpoints in the model region. The **GENERATE merge** command can be used to ensure that separate primitives are connected properly. All gridpoints along matching faces of zone primitives must fall within a specified tolerance, for two primitives to be merged. Alternatively, the **ATTACH** command is available to connect primitive meshes of different zone sizes. *FISH* can be used to adjust the final mesh, if necessary, to conform to the surfaces of the model region. Separate volume regions within the final mesh can be defined by using the **GENERATE surface** command. The following sections describe the use of each of these facilities to create a *FLAC3D* mesh. See Section 1.3 in the **Command Reference** for a detailed description of the **GENERATE** and **ATTACH** commands.

---

* Previous versions of *FLAC3D* also contained an automatic grid adjustment algorithm that used an iteration process to conform the grid to fit within a specified volume. This approach was found to be less efficient than building the grid using primitive shapes and has been discontinued.

3.2.1.1 Zone Generation

The *FLAC3D* grid is generated with the **GENERATE zone** command. This command actually accesses a library of primitive shapes; each shape has a specific type of grid connectivity. The primitive shapes available in *FLAC3D*, listed in order of increasing complexity, are summarized, with their associated keywords, in Table 3.2.

Table 3.2 Primitive mesh shapes available with the* GENERATE zone *command

Keyword	Definition
brick	brick-shaped mesh
wedge	wedge-shaped mesh
uwedge	uniform wedge-shaped mesh
tetra	tetrahedral-shaped mesh
pyramid	pyramid-shaped mesh
cylinder	cylindrical-shaped mesh
dbrick	degenerate brick-shaped mesh
radbrick	radially graded mesh around brick
radtunnel	radially graded mesh around parallelepiped-shaped tunnel
radcylinder	radially graded mesh around cylindrical-shaped tunnel
cshell	cylindrical shell mesh
cylint	intersecting cylindrical-shaped tunnels
tunint	intersecting parallelepiped-shaped tunnels

As you have already seen in Section 2.2, **GENERATE zone** commands can be used alone to create a zoned model. If the 3D domain consists of simple shapes, the primitives can be applied individually, or connected together to create the *FLAC3D* grid.

As an example, a quarter-symmetry model can be created for a cylindrical tunnel with the command

```
gen zone radcyl size 5 10 6 12 fill
```

The **size** keyword defines the number of zones in the grid. For the cylindrical tunnel, each entry following the **size** keyword corresponds to the number of zones in a specific direction. In this case, there are five zones along the inner radius of the cylindrical tunnel, ten zones along the axis of the tunnel, six zones along the circumference of the tunnel, and twelve zones between the periphery of the tunnel and the outer boundary of the model. Figure 3.2 shows the model grid. The **fill** keyword is given to fill the tunnel with zones.

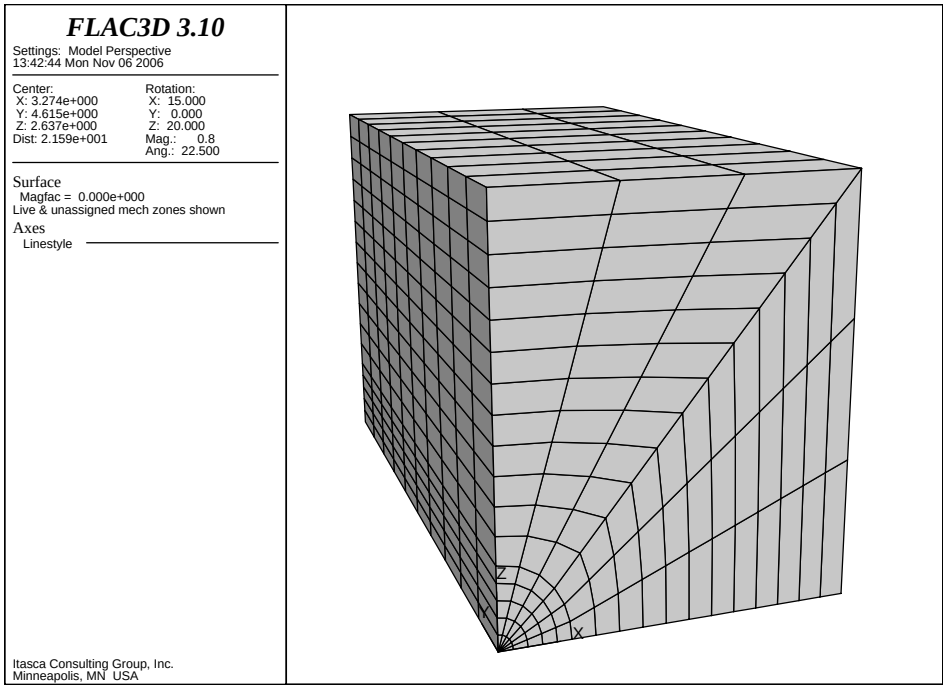

Figure 3.2 Grid for cylindrical tunnel model

In addition to **size** and **fill**, there are several other keywords available to define the characteristics of the primitive shapes. The available characteristic keywords for primitive shapes are summarized in Table 3.3. You should refer to Figures 1.4 through 1.16 in the **Command Reference** to identify which keywords and numerical entries are applicable for each primitive shape. For example, refer to Figure 1.13 in the **Command Reference** to check the order in which the **size** entries (*n1*, *n2*, *n3* and *n4*) should be entered for the cylindrical tunnel.

Table 3.3 Characteristics keywords for* GENERATE zone *primitive shapes

Keyword	Definition
dimension	dimensions of the interior regions
edge	edge length for the sides of the mesh
fill	fill the interior region with zones
p0 through **p16**	reference (corner) points for the shape
ratio	geometric ratio used to space zones
size	number of zones for each shape

The **ratio** keyword is of particular significance when designing a grid to provide an accurate solution without requiring an excessive number of zones. For example, if fine zoning is required immediately around the periphery of the cylindrical tunnel in order to provide a more accurate representation of high-stress gradients, **ratio** can be used to adjust the zone size to be small close to the tunnel, and gradually increase in size away from the tunnel.

To see the effects of using the **ratio** keyword, type the command

```
gen zone radcyl size 5 10 6 12 ratio 1 1 1 1.2
```

Each **size** entry is controlled by a **ratio**. In this example, the fourth **size** entry has a geometric ratio of 1.2 — i.e., each successive zone is 1.2 times larger than the preceding zone, moving from the tunnel periphery to the outer boundary (see Figure 3.3). A ratio smaller than 1.0 can be given to change from an increasing to a decreasing geometric ratio.

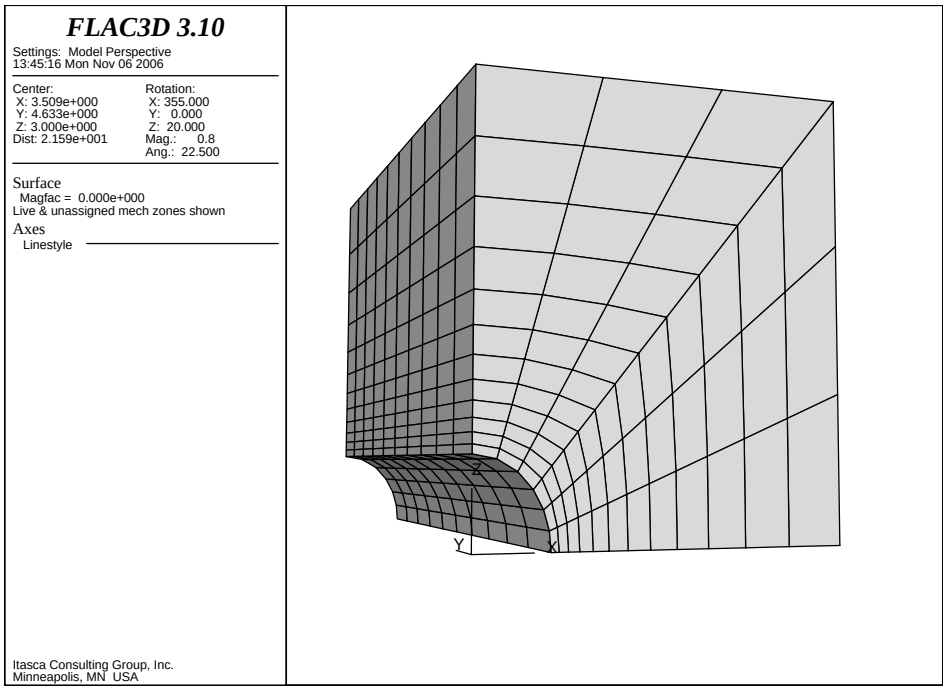

Figure 3.3 Radially graded grid around cylindrical tunnel

Sizing the grid for accurate results, but with a reasonable number of zones, can be complicated. Three factors should be remembered:

1. Finer meshes lead to more accurate results in that they provide a better representation of high-stress gradients.

2. Accuracy increases as zone aspect ratios tend to unity.

3. If different zone sizes are needed, then the more gradual the change from the smallest to the largest, the better the results.

The examples in the following sections illustrate some applications of these factors.

Several **GENERATE zone** commands can be given to connect two or more primitive shapes together to build a grid. For example, to build a horseshoe-shaped tunnel, the **radcylinder** and **radtunnel** shapes can be used as demonstrated in Example 3.1.

Example 3.1 Building a horseshoe-shaped tunnel — half model

```
gen zone radcyl size 5 10 6 12 rat 1 1 1 1.2 &
                p0 0,0,0 p1 100,0,0 p2 0,200,0 p3 0,0,100
gen zone radtun size 5 10 5 12 rat 1 1 1 1.2 &
                p0 0,0,0 p1 0,0,-100 p2 0,200,0 p3 100,0,0
```

Figures 1.12 and 1.13 in the **Command Reference** should be consulted when building these shapes. The model boundary dimensions are 100 × 200 × 100; the boundary coordinates are defined with the **p0**, **p1**, **p2** and **p3** keywords. The grid is shown in Figure 3.4. Note that the **radtunnel** shape is turned 90° to fit beneath the **radcylinder** shape. This is accomplished by specifying different p1-, p2- and p3-coordinate entries for the **radtunnel** shape.

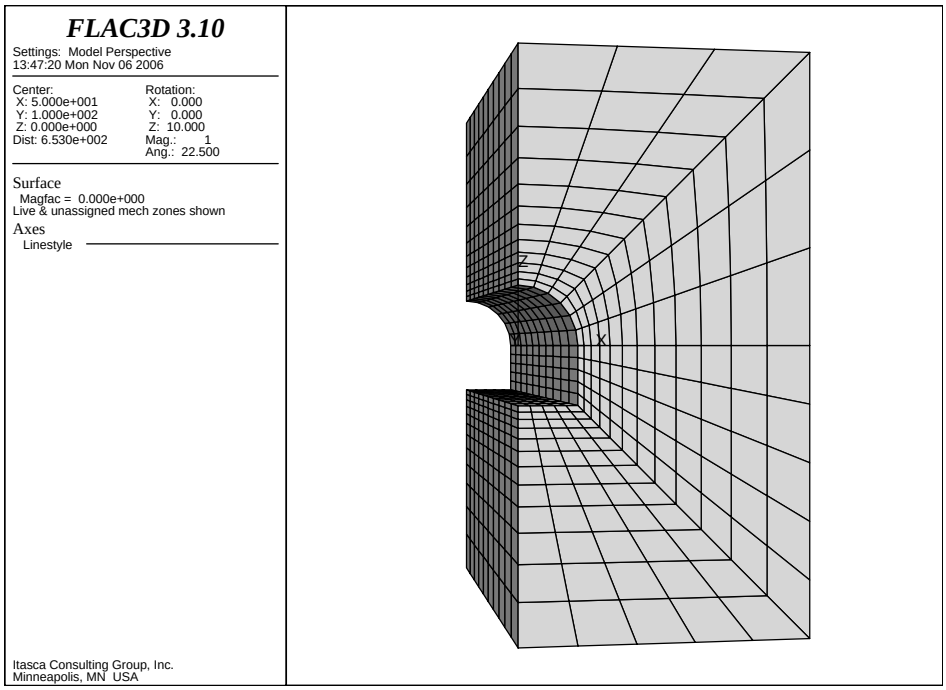

Figure 3.4 Horseshoe-shaped tunnel made from* radcylinder *and* radtunnel *primitives

With **GENERATE zone**, two additional options are available to assist with the creation of a grid composed of multiple shapes: **GENERATE zone copy** and **GENERATE zone reflect**. The **copy** keyword is used to copy a shape or shapes to a new position by adding an offset vector to all the gridpoints. The **reflect** keyword is used to reflect the shape or shapes across a symmetry plane. Example 3.2 shows the additional command needed to reflect the geometry created by the earlier commands.

Example 3.2 Building a horseshoe-shaped tunnel — full model

```
gen zone radcyl size 5 10 6 12 rat 1 1 1 1.2 &
                p0 0,0,0 p1 100,0,0 p2 0,200,0 p3 0,0,100
gen zone radtun size 5 10 5 12 rat 1 1 1 1.2 &
                p0 0,0,0 p1 0,0,-100 p2 0,200,0 p3 100,0,0
gen zone reflect dip 90 dd 270 origin 0,0,0
```

The resulting grid is shown in Figure 3.5. The symmetry plane is a vertical plane (located by the **dip**, **dd** and **origin** keywords) coincident with the x = 0 plane. Note that dip angle (**dip**) and dip direction (**dd**) assume that x corresponds to "East," y to "North" and z to "Up."

A third option, the **GENERATE point** command, is available to position single points in the model region. This is useful for positioning gridpoints of zones. The **point** can be assigned directly to a gridpoint, rather than specifying global coordinates. Section 3.2.2 presents an example use of **GENERATE point** to position the invert of two tunnels of different sizes at the same elevation.

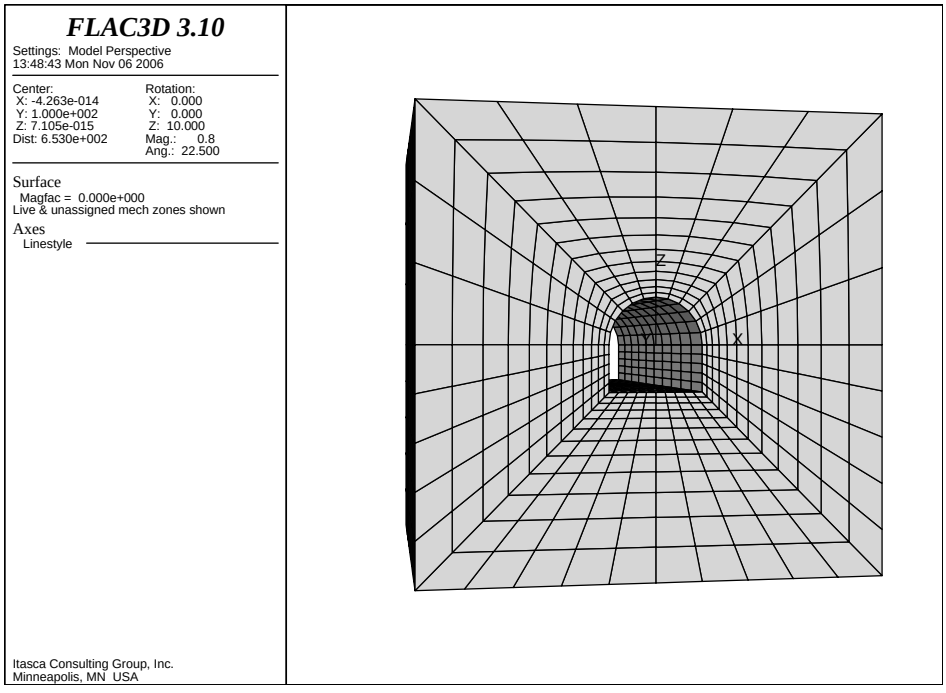

Figure 3.5 Complete horseshoe-shaped tunnel made from the* reflect *keyword

3.2.1.2 Connecting Adjoining Primitive Shapes

When building a geometry out of primitives, the sides of the primitives *must* connect to form an unbroken continuum. During execution of a **GENERATE zone** command, a check is made for each boundary gridpoint against the boundary gridpoints of zones that already exist. Internal gridpoints are not checked. If two boundary gridpoints fall within a tolerance of 1×10^{-7} (relative to the magnitude of the gridpoints position vector) of each other, they are assumed to be the same point, and the first gridpoint is used rather than creating a new one for all subsequent calculations.

The user is responsible for ensuring that all gridpoints along adjoining primitives correspond to one another. The use of reference points with the command **GENERATE point** during model creation can be useful to make sure that the bounding brick is specified correctly for both primitives. Make sure that the number of zones is correct and that the **ratio**s used for the zone distribution are consistent. Note that if the ratio for one primitive is going the opposite direction of the other, the inverse ratio should be used for one of the primitives to ensure that boundary gridpoints match.

This version of *FLAC3D* does not issue a warning message if gridpoints at boundaries do not match. It is helpful to use the **PLOT sketch** or **PLOT boundary** command to check boundary gridpoints visually. Localized velocity anomalies will be observed at non-matching gridpoints in the model when the calculation is started. If some gridpoints are found not to match, the **GENERATE merge** command can be used to merge these gridpoints after the **GENERATE zone** command has been applied.

The **ATTACH** command can be used to connect primitives with different zone sizes. There are some restrictions, though, to the range in zone size that may be specified with this approach. For the most accurate calculations, the ratio of zone sizes should be a multiple integer ratio (e.g., 2 to 1, 3 to 1, 4 to 1). It is recommended that the ratio be tested first by running the model under elastic conditions. If a discontinuity is observed in the displacement, or stress distribution across the attached grids, then the ratio of zone sizes may need to be adjusted. However, if the discontinuity is small and far from the region of interest, it may not have a significant influence on the calculation.

Example 3.3 illustrates the use of the **ATTACH** command and the effect of different zone sizes. A brick primitive with a zone dimension of 0.5 is connected to a brick primitive with a zone dimension of 1. The resulting z-displacement contours are shown in Figure 3.6.

Example 3.3 Two unequal sub-grids

```
gen zone brick size 4 4 4 p0 0,0,0 p1 4,0,0 p2 0,4,0 p3 0,0,2
gen zone brick size 8 8 4 p0 0,0,2 p1 4,0,2 p2 0,4,2 p3 0,0,4
attach face range z 1.9 2.1
model elas
prop bulk 8e9 shear 5e9
fix z range z -.1 .1
fix x range x -.1 .1
fix x range x 3.9 4.1
fix y range y -.1 .1
fix y range y 3.9 4.1
apply szz -1e6 range z 3.9 4.1 x 0,2 y 0,2
hist unbal
solve
save att.sav
```

To test the accuracy, we do a similar run, but for a single grid with a constant zone dimension of 0.5. The data file is given in Example 3.4. The results are shown in Figure 3.7. This plot is almost identical to that in Figure 3.6.

Example 3.4 A single grid for comparison to two sub-grids

```
gen zone brick size 8 8 8 p0 0,0,0 p1 4,0,0 p2 0,4,0 p3 0,0,4
model elas
prop bulk 8e9 shear 5e9
fix z range z -.1 .1
fix x range x -.1 .1
fix x range x 3.9 4.1
fix y range y -.1 .1
fix y range y 3.9 4.1
apply szz -1e6 range z 3.9 4.1 x 0,2 y 0,2
hist unbal
solve
save noatt.sav
```

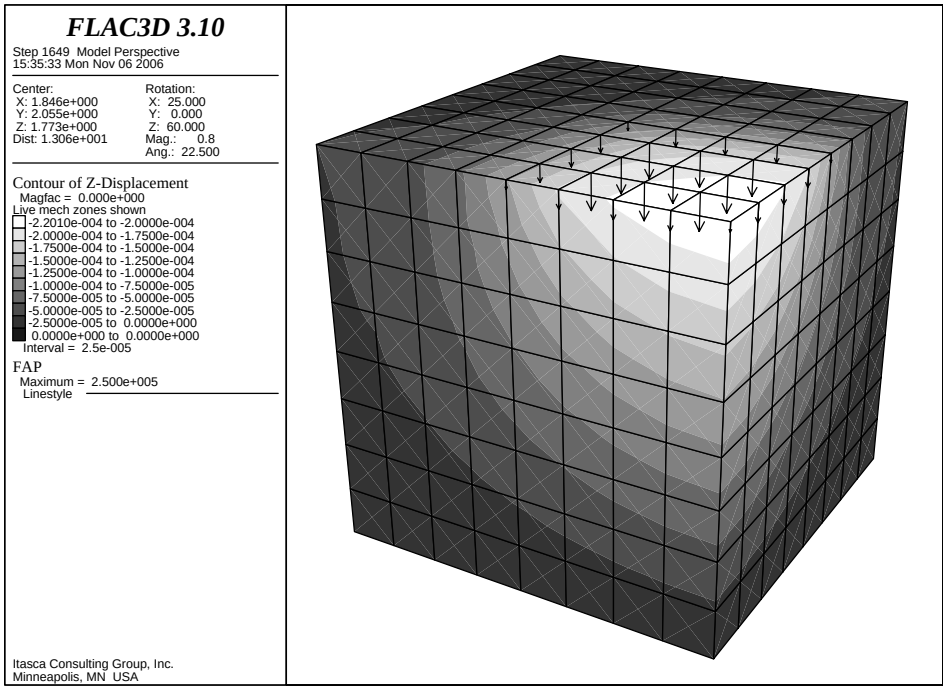

Figure 3.7 z-displacement contours in single grid

3.2.2 Fitting the Grid to Simple Shapes

The intention of grid generation is to fit the model grid to the physical region under study. For simple geometries, the **GENERATE zone** command is all that is required to generate a model grid to fit the problem domain. To determine whether **GENERATE zone** is sufficient, try defining the problem domain by one or more of the primitive shapes listed in Table 3.2 (see Table 1.3 in the **Command Reference** for sketches of these shapes).

For example, consider a problem geometry involving three parallel tunnels (a service tunnel located midway between two larger main tunnels). The three tunnels are all cylindrical in shape, so the **radcylinder** primitive shape is the logical choice to build the tunnel grids. A vertical symmetry plane may be assumed to exist along the centerline of the service tunnel. Thus, it is only necessary to create a mesh for one main tunnel and half of the service tunnel.

We have two important concerns when building any model: (1) the density of zoning required for an accurate solution in the region of interest; and (2) how the location of the grid boundaries influence model results.

It is important to have a high density of zoning in regions of high stress- or strain-gradients. Often, it is possible to perform two-dimensional analyses to define these regions. For this problem, a 2D *FLAC* calculation can easily be run to determine an acceptable density of zones around the tunnels. For demonstration purposes, we select a zone size of roughly one-half the service tunnel radius for the zones surrounding the tunnels.

The first step in grid generation for this problem is to use **radcylinder** primitives to create the grids for the tunnels. The complicating factor is that the tunnels are of different sizes and have the same invert elevation. The service tunnel has a radius of 3 m, and the main tunnels have a radius of 4 m. The length of the model corresponds to a 50 m length of the tunnels. Example 3.5 shows the commands to create the grid surrounding the tunnels.

Example 3.5 Creating a grid for two tunnels with the same invert elevation

```
; main tunnel
gen zon radcyl  p0 15 0 0 p1 23 0 0 p2 15 50 0 p3 15 0 8 &
                size 4 10 6 4 dim 4 4 4 4 rat 1 1 1 1 fill
gen zon reflect dip 90 dd 90 orig 15 0 0
gen zon reflect dip 0 ori 0 0 0
; service tunnel
gen point id 1 (2.969848,0.0,-0.575736)
gen point id 2 (2.969848,50.0,-0.575736)
gen zon radcyl  p0 0 0 -1 p1 7 0 0 p2 0 50 -1 p3 0 0 8 p4 7 50 0 &
                p5 0 50 8 p6 7 0 8 p7 7 50 8 p8 point 1 p10 point 2 &
                size 3 10 6 4 dim 3 3 3 3 rat 1 1 1 1
gen zon radcyl  p0 0 0 -1 p1 0 0 -8 p2 0 50 -1 p3 7 0 0 p4 0 50 -8 &
                p5 7 50 0 p6 7 0 -8 p7 7 50 -8 p9 point 1 p11 point 2 &
                size 3 10 6 4 dim 3 3 3 3 rat 1 1 1 1
```

The main tunnel grid is created first: one-quarter of the grid is generated; then the grid is reflected across horizontal and vertical planes to create the grid for the entire tunnel. The **reflect** option cannot be used for the service tunnel, because the invert of the service tunnel is required to be at the same elevation as the main tunnel. The vertices locating the service tunnel radius must be adjusted in the **radcylinder** primitive. This is done by first defining these locations using the **GENERATE point** command. The corner points **p8** and **p10** in one **radcylinder** primitive, and **p9** and **p11** in the other primitive, are located at the reference points. This ensures that the two primitives will match at boundary gridpoints when the grid is generated. Figure 3.8 shows the grid for the tunnels. The vertical plane at $x = 0$ is a symmetry plane.

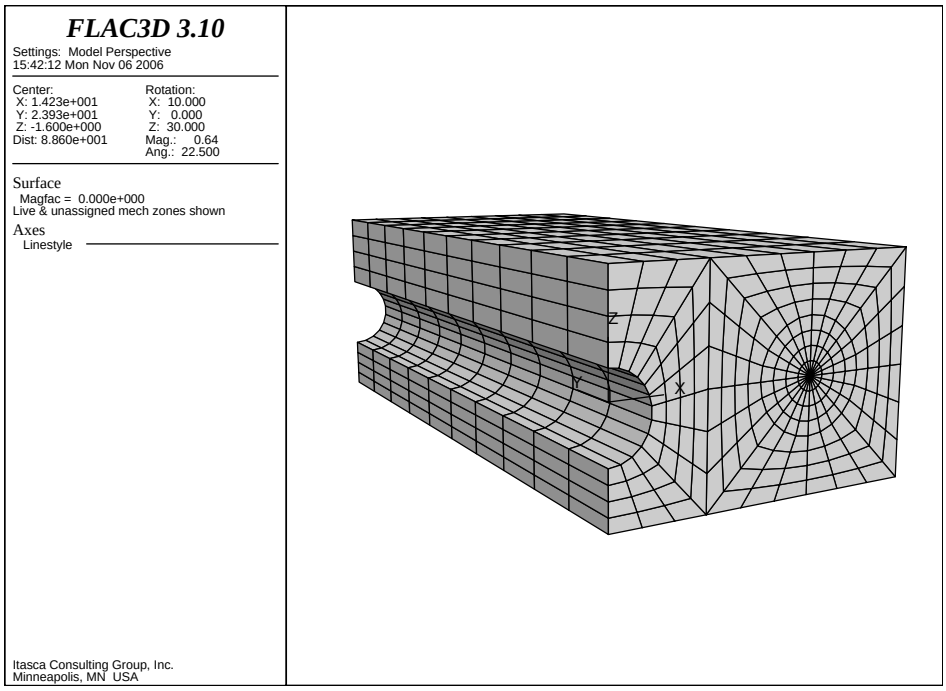

Figure 3.8 Inner grid for the service and main tunnels

For this model, we begin with the main tunnel filled with zones and the service tunnel not filled. The excavation and construction stages analyzed with this model are described later, in Section 3.5. Before the main tunnel is excavated, we define a liner for the service tunnel; this is accomplished with the **SEL shell** command, which creates a tunnel lining composed of structural shell elements*. Structural elements should generally be used to represent thin tunnel liners because they provide a more accurate representation of liner bending than a liner composed of finite-difference zones. See Section 1 in **Structural Elements** for detailed information on the structural element logic in *FLAC3D*. Example 3.6 gives the command to create the liner.

---

* This creates a liner that is rigidly attached to the grid. A liner with a connection to the grid that can slide/separate can be specified with the **SEL liner** command.

Example 3.6 Creating a liner in the service tunnel

```
; liner
sel shell range cyl end1 0 0 -1  end2 0 50 -1  rad 3
```

The liner contains 240 structural shell elements and is connected to the *FLAC3D* grid at 143 structural-node links. The grid with the liner is shown in Figure 3.9.

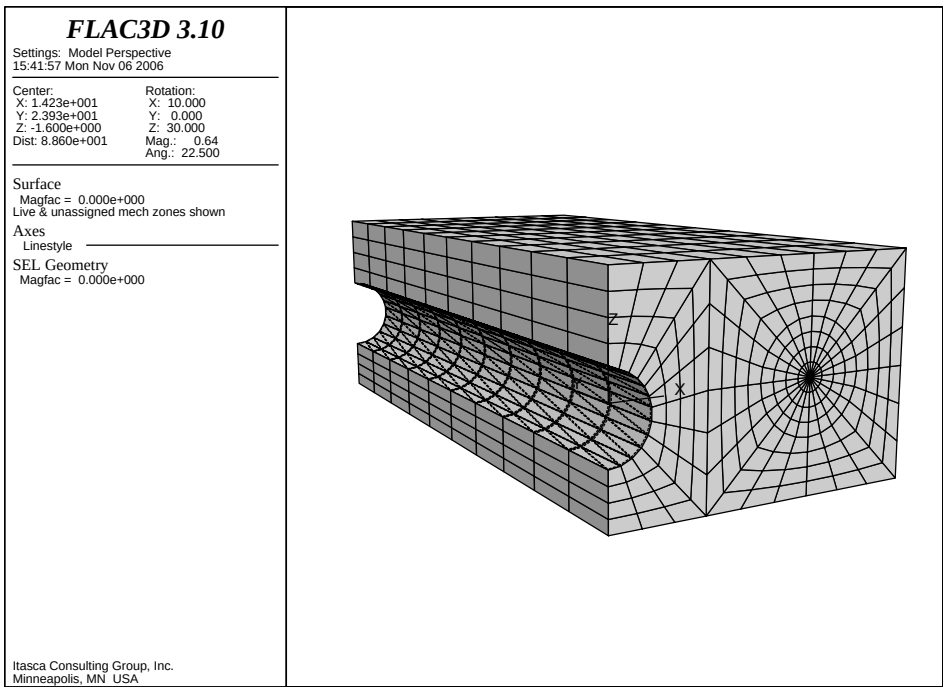

Figure 3.9 Liner elements in service tunnel

Finally, the outer-boundary grid is created around the tunnel grid. For analyses of underground excavations, boundaries should be located roughly ten excavation diameters from the excavation periphery. The distance, however, can vary depending on the purpose of the analysis. If failure is of primary concern, then the model boundaries may be closer; if displacements are important, then the distance to the boundaries may need to be increased.

It is important to experiment with the model to assess boundary effects. Begin with a coarse two-dimensional grid, using *FLAC*, and bracket the boundary effect using fixed and free boundary-conditions while changing the distance to the boundary. The resulting effect of changing the boundary can then be evaluated in terms of differences in stress or displacement calculated in the region of interest. The boundary location should then be tested with a coarse grid in *FLAC3D*.

We create the boundary grid with the **radtunnel** and **brick** primitives for this model. The **reflect** option is used to reflect the grid across the plane at $z = 0$. We use the **range** keyword to restrict the action of **reflect**. See Example 3.7.

The final grid for this problem is shown in Figure 3.10. The **GROUP** command is used to identify the main tunnel in the figure.

Example 3.7 Creating the boundary grid

```
; outer boundary
gen zone radtun p0 7 0 0 p1 50 0 0 p2 7 50 0 p3 15 0 50 p4 50 50 0 &
                p5 15 50 50 p6 50 0 50 p7 50 50 50 &
                p8 23 0 0 p9 7 0 8 p10 23 50 0 p11 7 50 8 &
                size 6 10 3 10 rat 1 1 1 1.1
gen zone brick  p0 0 0 8 p1 7 0 8 p2 0 50 8 p3 0 0 50 &
                p4 7 50 8 p5 0 50 50 p6 15 0 50 p7 15 50 50 &
                size 3 10 10 rat 1 1 1.1
gen zon reflect dip 0 ori 0 0 0 range x 0 23 y 0 50 z 8 50
gen zon reflect dip 0 ori 0 0 0 range x 23 50 y 0 50 z 0 50
group service range cyl end1   0 0 -1  end2   0 50 -1 rad 3
group main    range cyl end1  15 0  0  end2  15 50  0 rad 4
```

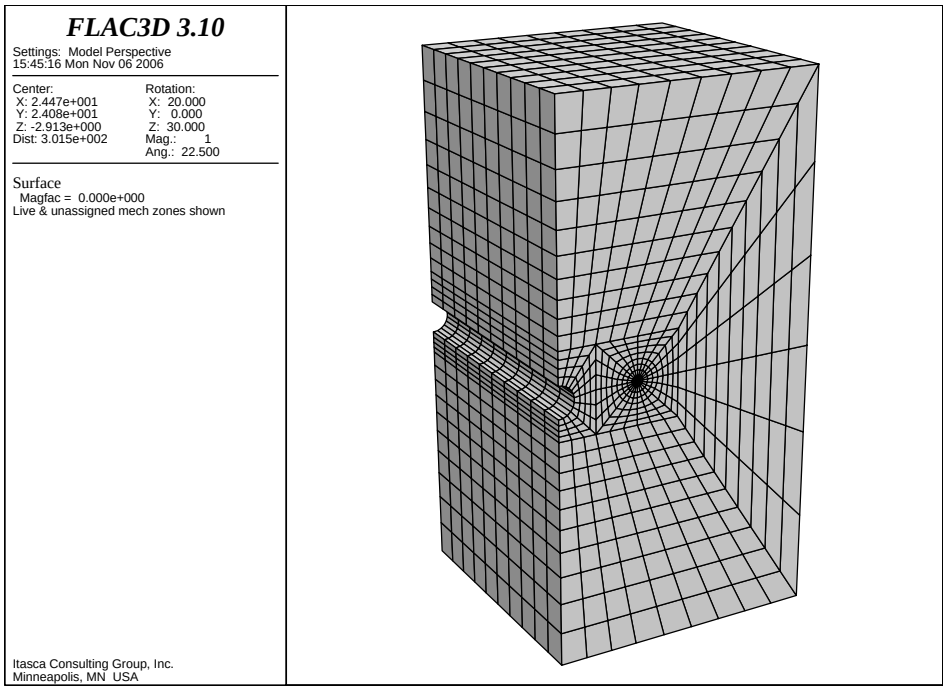

Figure 3.10 Complete grid for service and main tunnels

3.2.3 Grid Generation with FISH

FISH can be used to specify a geometric shape that is not readily available by using the built-in primitives in *FLAC3D*. For example, an irregular surface on a model can be made by using *FISH* to adjust gridpoints via a user-specified topology function (see Example 3.26).

It is also possible to create your own primitive shapes using *FISH*. In the following example, we create a radially graded mesh around a spherical cavity. Only one-eighth of the grid is generated. The grid can be reflected to create the complete spherical cavity.

A **radbrick** primitive is the basis for creating our "radsphere" shape. We first define parameters that describe the sphere within a cube: the radius of the spherical cavity; the length of the outer cube edge; the number of zones along the outer cube edge; and the number of zones in the radial direction from the inner cube to the outer cube. Then we define a **radbrick** such that the spherical cavity will be inscribed in the inner cube. Example 3.8 lists the commands to create the initial grid for a geometric ratio of 1.2. The grid is shown in Figure 3.11.

Example 3.8 Parameters to create a radially graded mesh around a spherical cavity

```
def parm
  rad=4.0     ; radius of spherical cavity
  len=10.0    ; length of outer box edge
  in_size=6   ; number of zones along outer cube edge
  rad_size=10 ; number of zones in radial direction
end
parm
gen zone radbrick edge len size in_size in_size in_size rad_size &
  rat 1.0 1.0 1.0 1.2 dim rad rad rad
```

The gridpoints within the radbrick are now relocated to form the mesh around a spherical cavity. The *FISH* function **make_sphere** loops through all the gridpoints and remaps their coordinates using a linear interpolation along radial lines from the sphere origin to the gridpoints along the outer box sides. Example 3.9 shows the **make_sphere** *FISH* function, and Figure 3.12 shows the final grid.

Example 3.9 FISH function to position gridpoints for a mesh around a spherical shape

```
def make_sphere
; Loop over all GPs and remap their coordinates:
;  assume len>rad
  p_gp=gp_head
  loop while p_gp#null
; Get gp coordinate: P=(px,py,pz)
    px=gp_xpos(p_gp)
    py=gp_ypos(p_gp)
```

```
    pz=gp_zpos(p_gp)
; Compute A=(ax,ay,az)=point on sphere radially "below" P.
    dist=sqrt(px*px+py*py+pz*pz)
    if dist>0 then
      k=rad/dist
      ax=px*k
      ay=py*k
      az=pz*k
; Compute B=(bx,by,bz)=point on outer box boundary radially "above" P.
      maxp=max(px,max(py,pz))
      k=len/maxp
      bx=px*k
      by=py*k
      bz=pz*k
; Linear interpolation: P=A+u*(B-A)
      u=(maxp-rad)/(len-rad)
      gp_xpos(p_gp)=ax+u*(bx-ax)
      gp_ypos(p_gp)=ay+u*(by-ay)
      gp_zpos(p_gp)=az+u*(bz-az)
    end_if
    p_gp=gp_next(p_gp)
  end_loop
end
make_sphere
```

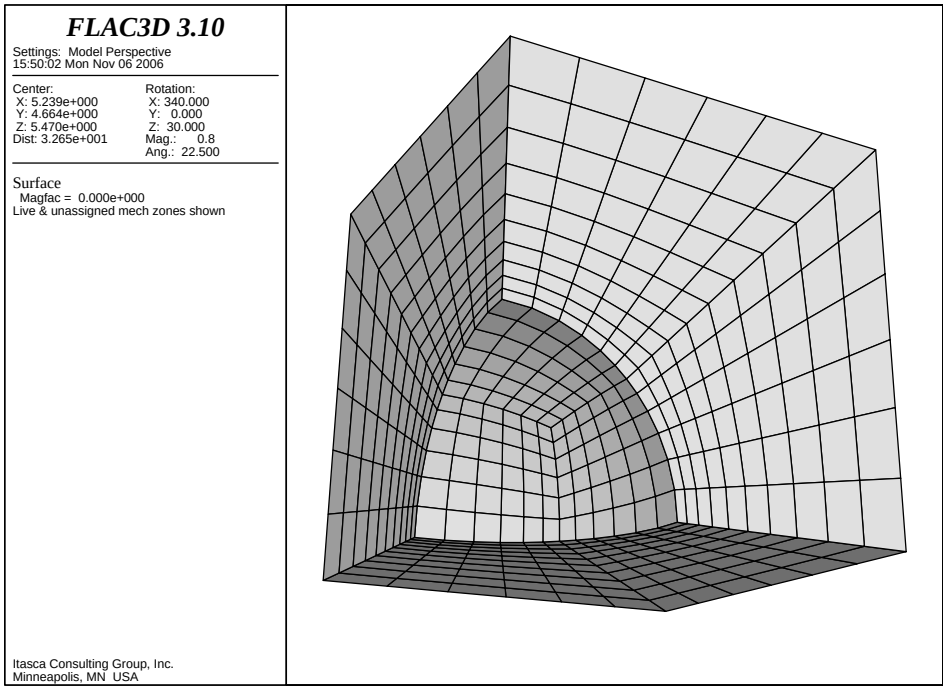

Figure 3.12 Radially graded mesh around a spherical cavity

3.2.4 Grid-Extrusion Tool

A special grid-generation tool is available to create a three-dimensional *FLAC3D* mesh by extruding a two-dimensional *FLAC* grid. The two-dimensional grid can be created directly within the grid-extrusion tool, or a *FLAC* data file can be loaded into the tool to create the extruded *FLAC3D* mesh. The grid-extrusion tool is accessed by pressing the FILE/FLAC EXTRUDE menu item. This brings up the *FLAC –> FLAC3D extrusion tool* as shown in Figure 3.13.

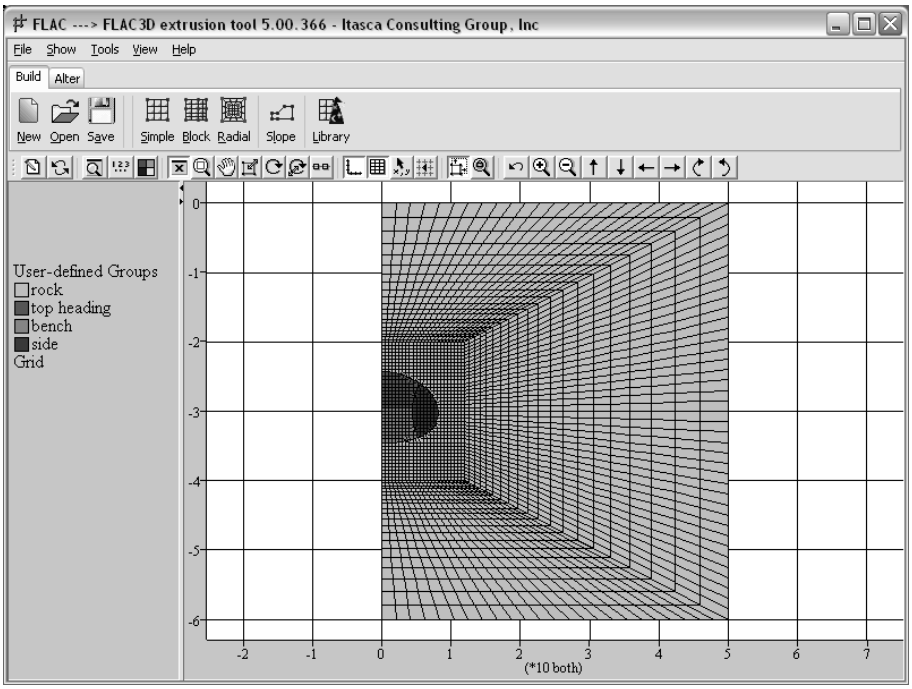

Figure 3.13 FLAC –> FLAC3D extrusion tool

The *FLAC –> FLAC3D extrusion tool* contains two toolbars to first create the grid (using the tools accessed from the BUILD tool tab) and then alter and extrude the grid (using the tools accessed from the ALTER tool tab).

The BUILD tab contains five tools to create a two-dimensional mesh. These tools are: SIMPLE, BLOCK, RADIAL, SLOPE and LIBRARY. The grid-generation tools define the general shape, spacial dimensions, zone density and gradation for a two-dimensional section. The operation of each of these tools is described in Section 1.2.1 in the ***FLAC-GIIC* Reference**.

After the two-dimensional grid is created, additional alterations or shape forming is done using the tools accessed from the ALTER tab. These tools are: MARK, SHAPE, TABLE, DELETE and GROUP. The MARK and SHAPE tools are used to define sub-regions and add additional shapes (e.g., excavation boundaries and layered materials) to the grid. The operation of these two tools is described in Section 1.2.2 in the ***FLAC-GIIC* Reference**. The TABLE tool can also be used to create a geometric table to locate

boundaries within a model grid; the geometric table can then be used to shape the model in the SHAPE tool. The TABLE tool operation is described in Section 1.2.6.2 in the ***FLAC-GIIC* Reference**.

The GROUP tool is used to assign group names to sets of zones within the grid. Each group is prescribed a group name that will be recognized as a *FLAC3D* **group**. The DELETE tool is used to remove (null) zones from the model. The operation of group assignment and zone deletion is similar to that for the assignment of materials (MATERIAL/ASSIGN) as described in Section 1.2.3.1 in the ***FLAC-GIIC* Reference**.

The two-dimensional grid can be "saved" at any time by either pressing the SAVE button in the BUILD tab, or by selecting the FILE/SAVE AS menu item. This will create a data file that contains all of the *FLAC* commands used to generate this grid.

The data file can be re-opened within the extrusion tool by using the OPEN button in the BUILD tab, or by selecting the FILE/OPEN menu item. A *FLAC*-generated data file can also be opened within the grid-extrusion tool. In this case, only the *FLAC* commands related to grid generation are recognized by the grid-extrusion tool; all other *FLAC* commands are ignored.

After the two-dimensional mesh is complete, the EXTRUDE tool is selected in order to extrude the grid to create a three-dimensional *FLAC3D* mesh. This opens a *Extrude 2D mesh to FLAC3D* dialog as shown in Figure 3.14. In order to extrude the mesh in a direction orthogonal to the two-dimensional plane, click on the EXTRUDE INTO ORTHOGONAL AXIS button. Parameters are then set in the dialog to select the length of the extruded mesh, and the number of zones and grid ratio in the extruded direction. The orientation of the two-dimensional mesh with respect to the *FLAC3D* global axes can also be specified. Note that *u* and *v* in the dialog correspond to the *x*- and *y*-directions, respectively, in the *FLAC* plane, and * is one of the three directions for extrusion in the *FLAC3D* coordinate system.

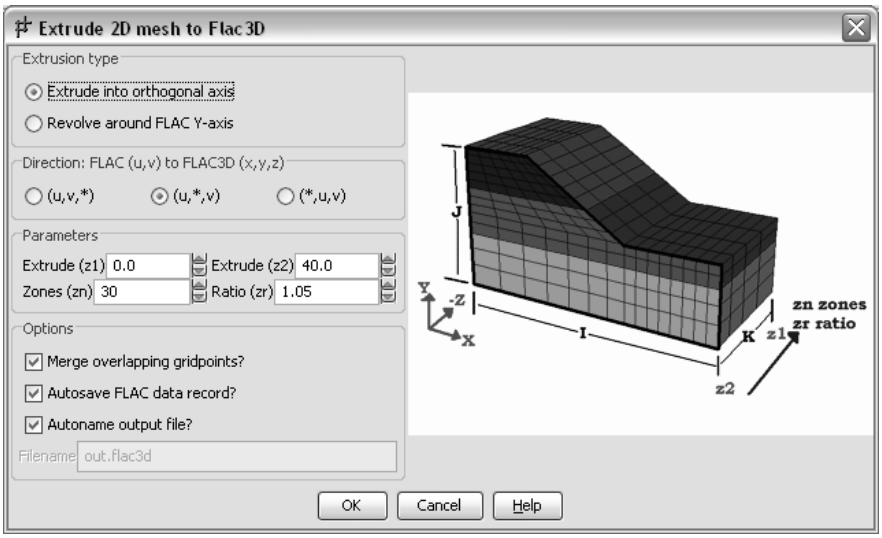

Figure 3.14 Extrude 2D mesh to FLAC3D dialog

If the two-dimensional grid is composed of sub-grids that are connected via **ATTACH** or **INTERFACE** *FLAC* commands, these commands are not transferred to equivalent *FLAC3D* commands. This must be done manually by the user after the *FLAC3D* mesh is created. Alternatively, if gridpoints along sub-grid boundaries coincide, these gridpoints can be merged when creating the *FLAC3D* mesh by checking the optional MERGE OVERLAPPING GRIDPOINTS? box in the *Extrude 2D mesh to FLAC3D* dialog.

When OK is pressed in the dialog, a grid output file (with the default filename "OUT.FLAC3D") is created and automatically imported into *FLAC3D* (using the procedure defined for the **IMPGRID** command). The *FLAC –> FLAC3D extrusion tool* is closed and operation returns to the *FLAC3D* command line.

Figures 3.13 through 3.15 illustrate the steps of importing a *FLAC* data file to create a two-dimensional grid, extruding the grid and creating a *FLAC3D* grid. (The input file is the grid-generation segment of the file "MSTUNNEL.DAT" for the multi-stage tunnel excavation described in Example Application 12 in the **Example Applications** volume of the *FLAC* manual.) The final *FLAC3D* mesh is shown in Figure 3.15.

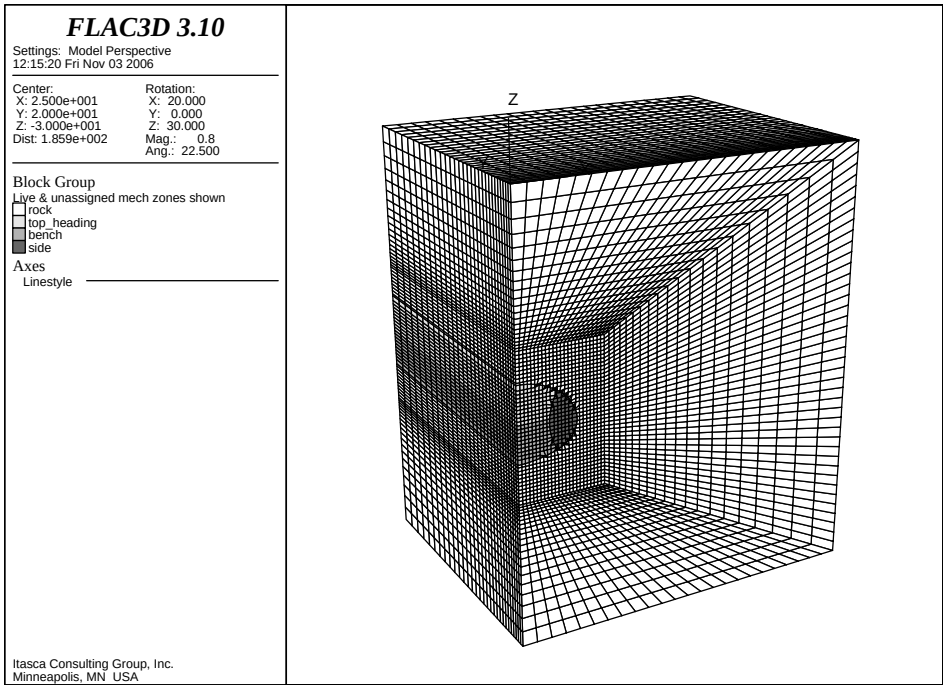

Figure 3.15 FLAC3D extruded mesh created from the FLAC data file for Example Application 12 in the FLAC manual

In addition to a linear extrusion of the two-dimensional grid, an extrusion can be made to revolve around the *FLAC* *y*-axis. As an example, the rock slope grid of Example Application 10 in the **Example Applications** volume of the *FLAC* manual is used to create a circular-shaped pit. The data file is the grid-generation segment of the file "ROCKSL.DAT" in Example Application 10. The file opened in the *FLAC –> FLAC3D extrusion tool* produces the grid shown in Figure 3.16. Note that the dimensions in the data file are translated by +40 m in both the *x*- and *y*-directions because positive coordinates are required when extruding about an axis of revolution.

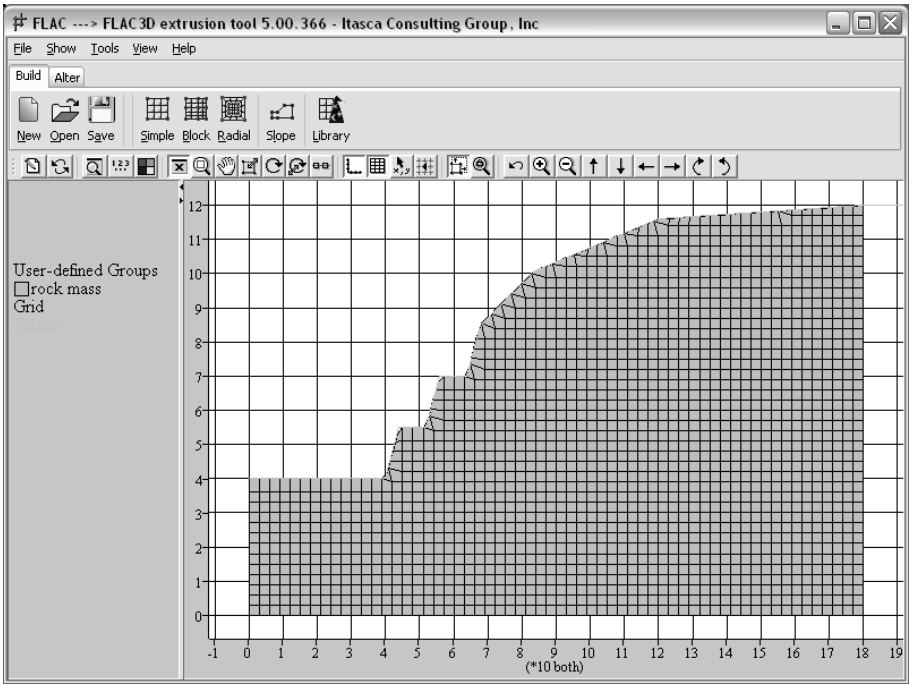

Figure 3.16 Rock Slope data file opened in the FLAC –> FLAC3D extrusion tool

The REVOLVE AROUND FLAC Y-AXIS box is checked in the *Extrude 2D mesh to FLAC3D* dialog as shown in Figure 3.17. The contents of the dialog change so that the angle of revolution and number of zones along the revolution axis can be entered. The orientation of the *FLAC3D* mesh relative to the axis of revolution can also be selected. Note that *u* and *v* in the dialog correspond to the *x*- and *y*-directions, respectively, in the *FLAC* plane, and * corresponds to one of the three directions for revolution in the *FLAC3D* coordinate system.

A 90° angle of revolution about the *y*-axis in *FLAC3D* is selected, as shown in Figure 3.17. The resulting three-dimensional mesh is shown in Figure 3.18.

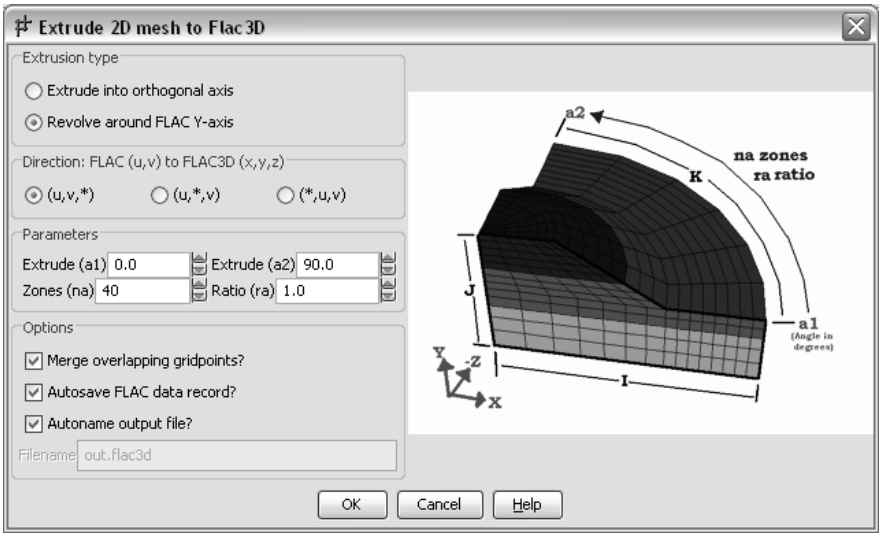

Figure 3.17 Extrude 2D mesh to FLAC3D dialog with extrusion set to revolve around FLAC y-axis

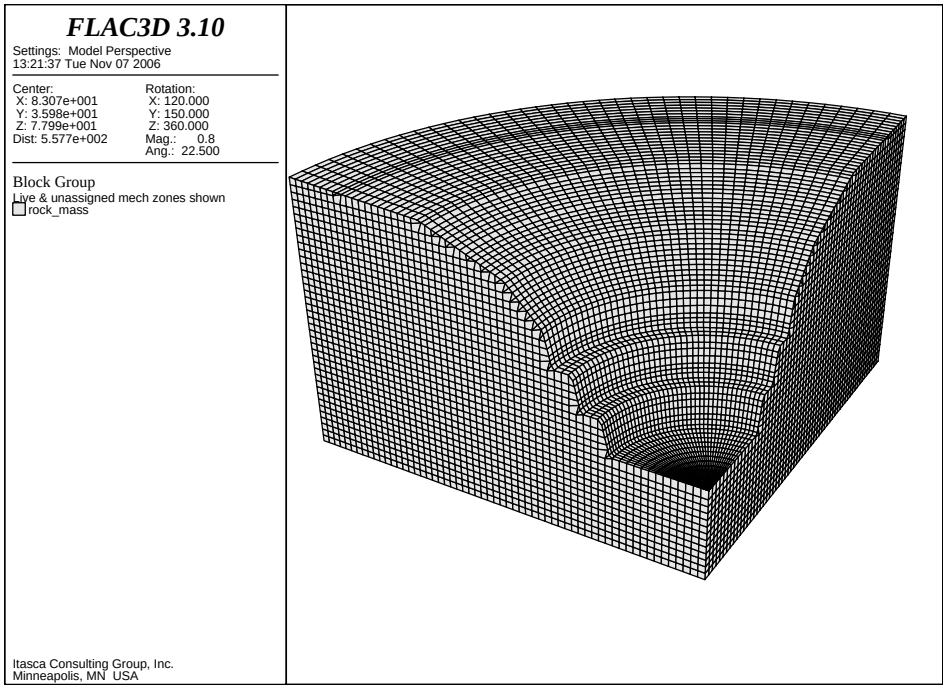

Figure 3.18 FLAC3D extruded mesh created from the FLAC data file for Example Application 10 in the FLAC manual

3.3 Boundary Conditions

The boundary conditions in a numerical model consist of the values of field variables (e.g., stress and displacement) that are prescribed at the boundary of the numerical grid. Boundaries are of two categories: real and artificial. Real boundaries exist in the physical object being modeled — e.g., a tunnel surface or the ground surface. Artificial boundaries do not exist in reality, but they must be introduced in order to enclose the chosen number of zones. The conditions that can be imposed on each type are similar; these conditions are discussed first. Then (in Section 3.3.4) some suggestions concerning the location and choice of artificial boundaries and the effect they have on the solution are made.

Mechanical conditions that can be applied at boundaries are of two main types: prescribed displacement or prescribed stress. A free surface is a special case of the prescribed-stress boundary. The two types of mechanical conditions are described in Sections 3.3.1 and 3.3.2.

3.3.1 Stress Boundary

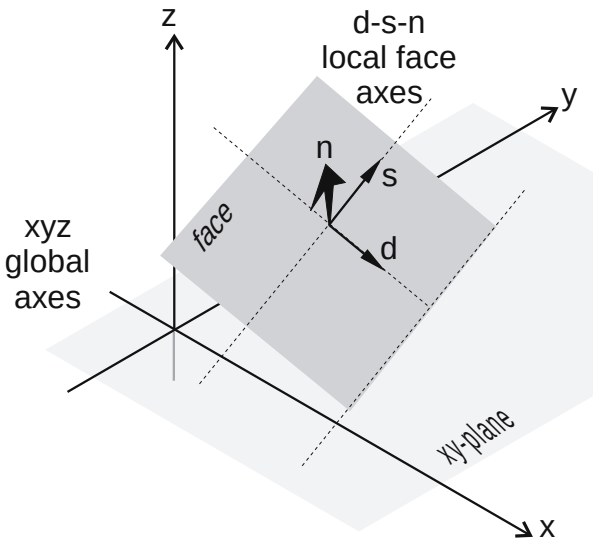
By default, the boundaries of a *FLAC3D* grid are free of stress and any constraint. Forces or stresses may be applied to any boundary, or part of a boundary, by means of the **APPLY** command. Individual components of the stress tensor are specified with the **sxx**, **syy**, **sxy**, **sxz** and **syz** keywords. For example, the command

```
apply szz = -1e5  sxz = -.5e5  range z -.1,.1
```

applies the given σ_{zz} and σ_{xz} components of a stress tensor to the model boundary falling within the range $-0.1 \leq z \leq 0.1$. All other stress components are zero.

Stress can be applied either in the global model x,y,z-directions, or in directions normal and tangential to the local boundary face. The keyword **nstress** applies a normal stress to a face, while keywords **dstress** and **sstress** apply shear stresses to the face. **dstress** is the stress component applied in the dip direction of the local face, and **sstress** is the stress component applied in the strike direction. The orientation of the local face axes is illustrated in Figure 3.19. Note that global (x,y,z)-axes stresses and local (d,s,n)-axes stresses cannot both be applied to the same face.

There are several things to note about this use of **APPLY** command. First, only those faces whose centroids lie within the coordinate range defined by **range** will be affected by the **APPLY** command. Second, compressive stresses have a *negative* sign, in accordance with the general sign convention for internal stresses in *FLAC3D*. Finally, *FLAC3D* actually applies the stress components as forces, or *tractions*, which result from a stress tensor acting on the given boundary plane; the tractions are computed whenever a **STEP** command is issued, and again every tenth step in large-strain mode.



The **d-s-n axes** form a right-handed coordinate system in which:

The **n-axis** is the outward normal to the face.

The **s-axis** is parallel to the projected intersection between the xy-plane and the face.

The **d-axis** is the line with the greatest negative z-component on the face (i.e., the direction of steepest descent on the plane).

Figure 3.19 Local face axes defined by (d) dip direction, (s) strike direction and (n) normal direction

Individual forces can also be applied to the grid by using the **xforce**, **yforce** and **zforce** keywords, which specify the *x*-, *y*- and *z*-components of an applied force vector. In this case, no account is taken of the boundary face area; the specified forces are simply applied to the given gridpoints.

The applied forces, or tractions calculated from applied stresses, can be viewed with the command **PLOT fap**. It is necessary to perform a **STEP 1** first in order to calculate the applied forces for viewing. For example, a stress boundary condition is applied normal to a boundary plane that has a dip angle of 60° and dip direction of 270°. Type the commands shown in Example 3.10.

Example 3.10 Applying a normal stress to a dipping boundary

```
gen zone brick size (4,4,4) p0 (0,0,0) p1 (4,0,0) &
     p2 (0,4,0) p3 (2,0,3.464)
model elastic
prop bulk 1e8 shear .3e8
apply nstress -1e6 range plane dip 60 dd 270 origin 0.1,0,0 above
```

The normal stress of -1×10^6 is applied to a boundary plane falling within the range defined by a plane with a dip direction of 270°, a dip angle of 60°, and above the position $x = 0.1$, $y = 0$, $z = 0$. The resulting applied forces can be seen by typing

```
step 1
plot grid green fap black
```

The plot in Figure 3.20 shows the forces applied to the grid as calculated from the normal stress and the boundary face areas. Note that the size of the force vectors is a function of the face areas over which the stress is applied.

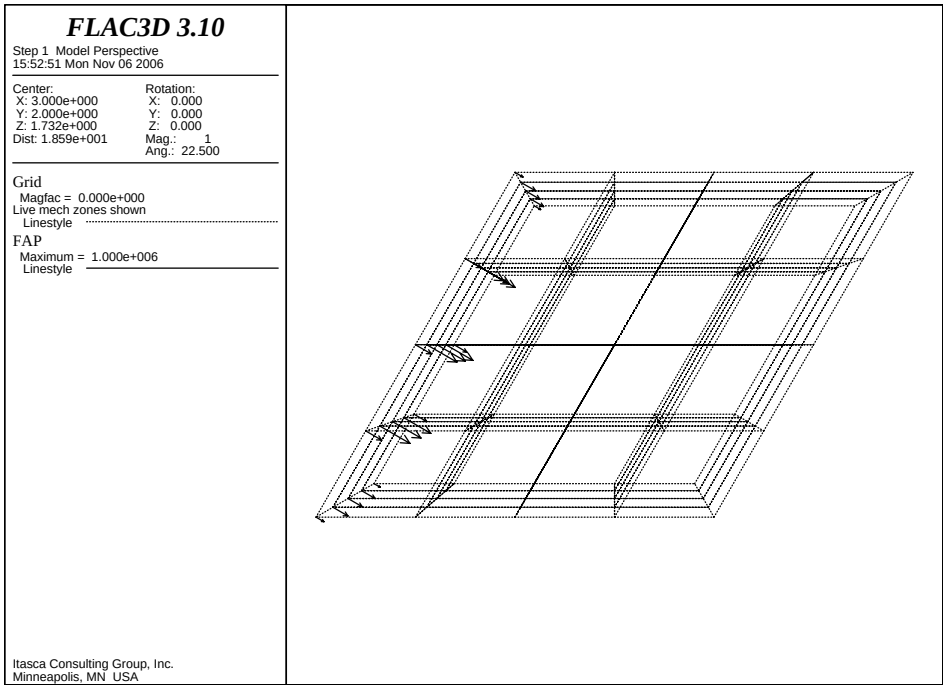


***Figure 3.20 Applied forces resulting from* APPLY nstress**

3.3.1.1 Applied Stress Gradients

The **APPLY** command may take the optional keyword **gradient**, which allows the applied stresses or forces to vary linearly over the specified range. The parameters following **gradient**, ***gx***, ***gy*** and ***gz***, specify the x-, y- and z-variation, respectively, for the stress- or force-component. The value varies linearly with distance from the global coordinate origin at (x = 0, y = 0, z = 0) — i.e.,

$$S = S^{(o)} + g_x x + g_y y + g_z z \tag{3.1}$$

in which $S^{(o)}$ is the value at the global coordinate origin at (x = 0, y = 0, z = 0), and g_x, g_y and g_z specify the variation of the value in the x-, y- and z-directions.

The operation of this feature is best explained by an example:

```
apply sxx -10e6 gradient 0,0,1e5 range z -100,0
```

The equation for the z-variation in stress-component σ_{xx} is

$$\sigma_{xx} = -10 \times 10^6 + (10^5)z$$

The σ_{xx}-stress at the origin (x = 0, y = 0, z = 0) is $\sigma_{xx} = -10 \times 10^6$; at $z = -100$, it is -20×10^6. At points in between, the stress is linearly scaled to the relative z-distance from the origin.

Typically, applied stress gradients are used to reproduce the effects of increasing stress with depth caused by gravity. It is important to make sure that the applied gradient is compatible with the stress gradient specified with the **INITIAL** command, and the value of gravitational acceleration given by the **SET gravity** command. See Section 3.4 for further comments on stress gradients.

3.3.1.2 Changing Boundary Stress

It may be necessary to alter the values of applied stresses during the course of a *FLAC3D* simulation. For example, the load on a footing may change. To effect a sudden change in an existing applied stress or load, a new **APPLY** command is given, with the range and stress component given *exactly as in the original command*, but with a changed value or variation. In this case, *FLAC3D* simply updates the stored stresses for that item on the list of applied loads. New values will replace existing values for any overlapping **APPLY** commands. It may be necessary to first remove boundary conditions (with **APPLY remove**) before updating a boundary stress.

In many instances, it may be necessary to change a boundary stress gradually. This is often required to minimize the shock to a sensitive system, especially if "path-dependence" of the solution is important (see Section 3.10.3). The data file in Example 3.11 causes the applied stress on the upper yz-face of a grid to be increased incrementally over a total of 100 steps, from an initial value of -1×10^3 to a final value of -1×10^5. We specify 100 *sub-steps* for each *super-step* in order to equilibrate the model at each load increment.

Example 3.11 Apply changing stress boundary with a FISH function

```
gen zone brick size 6 6 6
model elas
prop bulk 1e8 shear 7e7
fix x range x -0.1 0.1
def superstep
   loop ns (1,n_steps)
      x_stress = stress_inc
      command
         apply sxx add x_stress range x 5.9,6.1 y 0,6 z 0,2
         step 100
      end_command
   end_loop
end
set n_steps=100 stress_inc=-1e3
hist zone sxx 6,0,0
plot create sxx_hist
```

```
plot add hist 1
plot show
superstep
```

The stepping process is controlled from within the *FISH* function, because the **APPLY** command only takes effect when a **STEP** command is given. (See the discussion in Section 3.3.1.) The **WHILE_STEPPING** *FISH* statement cannot be used, because the applied forces will not be updated.

With the **history** multiplier keyword, the changing stress conditions can be described either by a *FISH* function or with a table. Example 3.11 can be altered to use a *FISH* history, as shown in Example 3.12.

Example 3.12 Apply changing stress boundary with a FISH history

```
gen zone brick size 6 6 6
model elas
prop bulk 1e8 shear 7e7
fix x range x -0.1 0.1
def x_stress
     x_stress = stress_inc * step
end
set stress_inc = -1e3
apply sxx 1.0 hist x_stress range x 5.9,6.1 y 0,6 z 0,2
hist zone sxx 6,0,0
hist x_stress
step 100
```

The *FISH* function **x_stress** is a multiplier applied at every calculation step. Note that a history of the multiplier can also be recorded.

Alternatively, the history can be specified via the **TABLE** command. The following data file performs the same function as the one above.

Example 3.13 Apply changing stress boundary with a table history

```
gen zone brick size 6 6 6
model elas
prop bulk 1e8 shear 7e7
fix x range x -0.1 0.1
table 1 0,0 100,-1e5
apply sxx 1.0 hist table 1 range x 5.9,6.1 y 0,6 z 0,2
hist zone sxx 6,0,0
step 100
```

By plotting the σ_{xx} history for Examples 3.11, 3.12 and 3.13, you will see that the three approaches for applying a changing bounding stress produce identical results. You will note that the calculation time is shorter for Examples 3.12 and 3.13 than for Example 3.11.

Stresses may also be applied to interior boundaries (e.g., tunnel walls). The rate of excavation of a tunnel can be simulated by controlling the rate at which the boundary stress is relaxed. This is shown by the following example for a gradual excavation of a circular tunnel in a Mohr-Coulomb material.

Example 3.14 Gradual excavation of a circular tunnel

```
gen zone radcyl p0 0 0 0 p1 add 18 0 0 p2 add 0 8 0 p3 add 0 0 18 &
    dim 1.75 1.75 1.75 1.75 ratio 1.0 .83 1.0 1.2 size 6 6 6 10

cyc 2000
```

No material failure is calculated in the tunnel walls when the boundary stress is relaxed. However, if the excavation is made instantaneously (i.e., the **APPLY nstress** command is removed from the data file), then the stress state in the first ring of zones reaches the failure surface during the unloading process (see Figure 3.21). Please note that this grid is too coarse to model plasticity accurately; a finer mesh is required around the tunnel because of the high-stress gradient. The purpose of the example is only to demonstrate the effect of different rates of change in boundary stress.

Another technique to relax stresses is demonstrated in Example 3.15. The geometry of this example is similar to that of Example 3.14 except that the interior of the tunnel to be excavated originally contains zones (i.e., the tunnel hasn't been excavated yet). The entire model is first brought to equilibrium, and then the material inside the tunnel is gradually softened. This softening is done through user defined *FISH* functions found in "ZONK3D.FIS" (see Example 3.16). ZONK3D will perform this softening process on all zones belonging to a group with a name of 'zonk'. It starts by replacing all of the zonk group zones with an elastic model with the same bulk and shear modulus as originally stored in the zone. The modulus and stresses in the zonk group zones are reduced by a constant factor (*FISH* variable factor) during an iterative process. The stresses are reduced to introduce a slight perturbation into the system so that it is no longer in equilibrium. The model is successively solved until the maximum Young's modulus (of one of the zonk zones) is below 5% of its maximum initial value. Once the model has passed this threshold, the zonk zones are made null (they could also be deleted). The user should experiment with the reduction factor and threshold value for Young's modulus for their specific case. ZONK3D.FIS is extremely useful for relaxing stresses in complicated geometries.

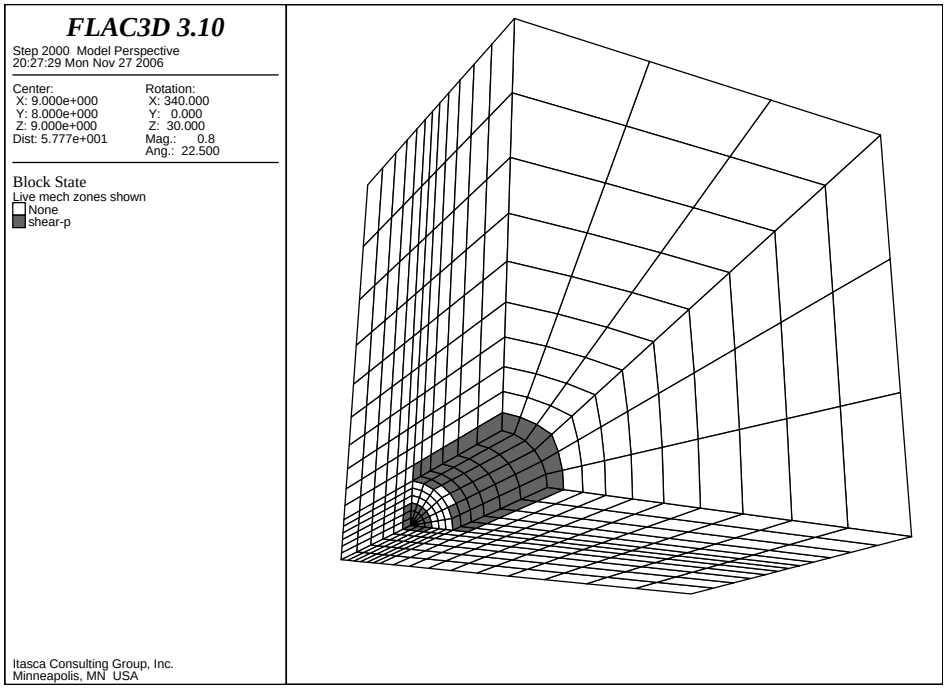

Figure 3.21 Plasticity state for instantaneous excavation of tunnel

3.3.1.3 Cautions and Advice

In this section, some miscellaneous difficulties with stress boundaries are described.

With *FLAC3D*, it is possible to apply stresses to the boundary of a body that has no displacement constraints (unlike many finite-element programs, which require some constraints). The body will react in exactly the same way as a real body would — i.e., if the boundary stresses are not in equilibrium, then the whole body will start moving. The following data file illustrates the effect.

Example 3.17 Spin when grid is not in equilibrium

```
gen zone brick size 6,6,6 p1 6,0,-1
model elas
prop bulk 8e9 shear 5e9
apply sxx -2e6 range x -0.1 0.1
apply sxx -2e6 range x 5.9 6.1
step 500
plot bound fap
plot grid disp
```

The plots produced from this example are given in Figures 3.22 and 3.23. The applied σ_{xx} stress causes horizontal forces to act on the body. Since the body is tilted, these forces give rise to a moment which causes the body to spin.

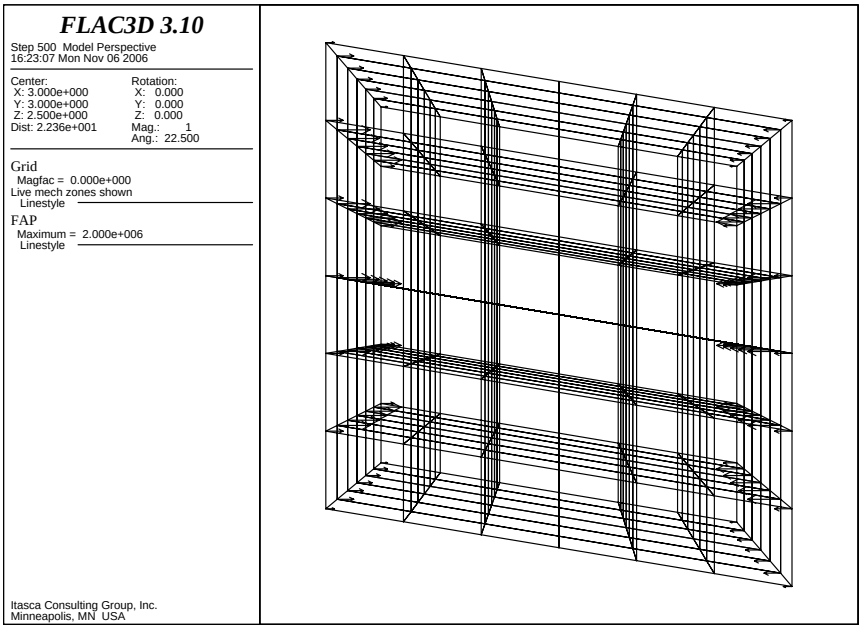

Figure 3.22 Applied horizontal forces on tilted body

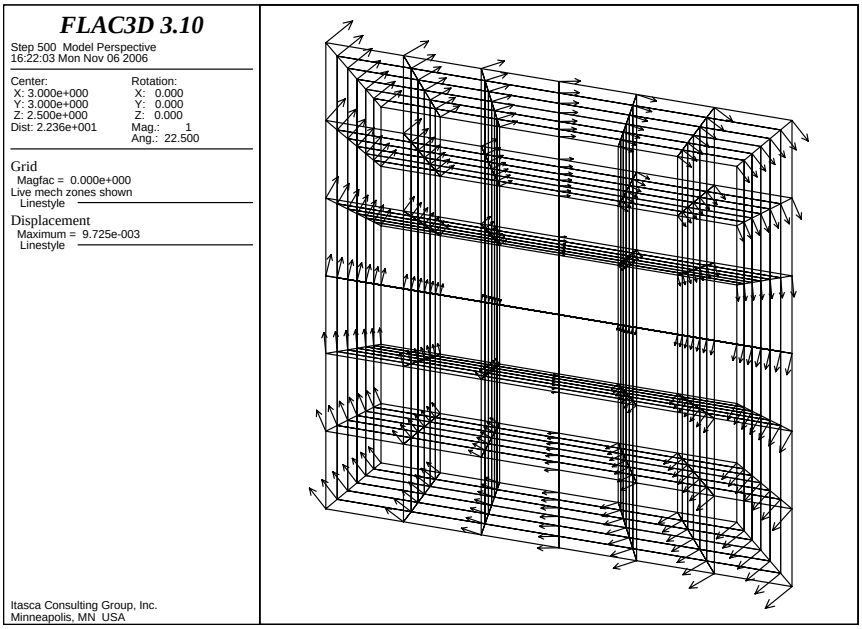

Figure 3.23 Rotational displacement induced by forces on tilted body

A similar, but more subtle, effect arises when material is excavated from a body that is supported by a stress boundary condition: the body is initially in equilibrium under gravity, but the removal of material reduces the weight. The whole body then starts moving upward, as demonstrated by the data file in Example 3.18.

Example 3.18 Uplift when material is removed

```
gen zone brick size 5,5,5
model elas
prop bulk 8e9 shear 5e9
set grav 0 0 -10
ini dens 1000
fix x range x -.1 .1
fix x range x 4.9 5.1
fix y range y -.1 .1
fix y range y 4.9 5.1
ini szz -5e4 grad 0 0 -1e4
app szz -5e4 range z -.1 .1
solve
model null range x 1,4 y 1 4 z 3 5
step 100
plot set plane dip 90 dd 180 origin 0,2.5,0
plot add surf plane behind yell
plot add vel plane behind black
plot show     ;body no longer in equilibrium
```

The uplift is shown in Figure 3.24. The difficulty encountered in running this data file can be eliminated by fixing the bottom boundary, rather than supporting it with stresses. Section 3.3.4 contains some information relating to the location of such artificial boundaries.

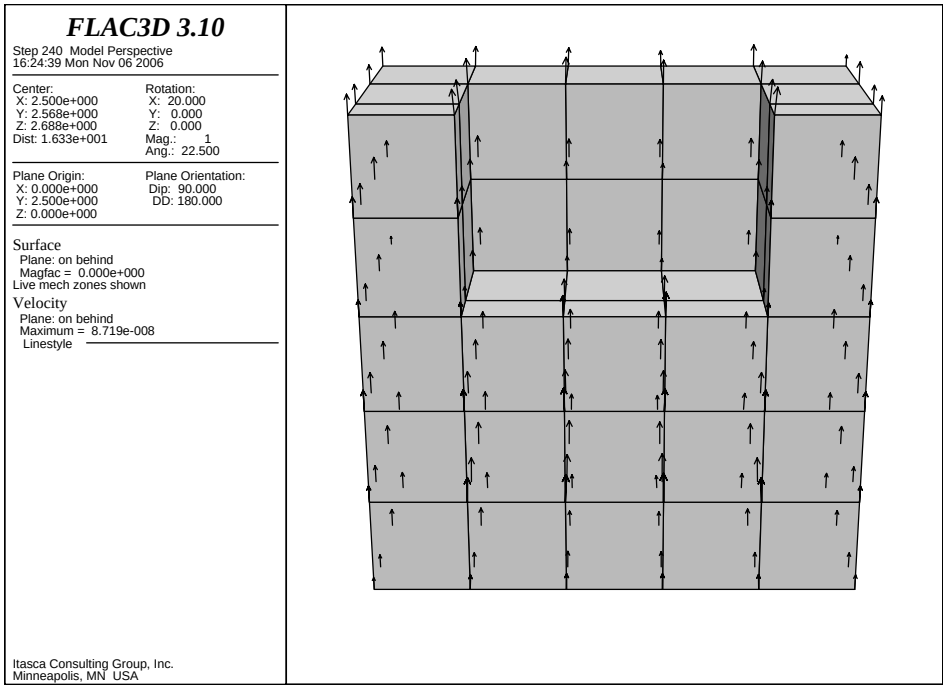

Figure 3.24 Uplift of model when material is removed

3.3.2 Displacement Boundary

Displacements cannot be controlled directly in *FLAC3D*; in fact, they play no part in the calculation process. In order to apply a given displacement to a boundary, it is necessary to prescribe the boundary's velocity for a given number of steps. If the desired displacement is D, a velocity V over N steps (where $N = D/V$) may be applied. In practice, V should be kept small and N large, in order to minimize shocks to the system being modeled. The **APPLY** command or the **FIX** and **INI** commands can be used to specify the velocities; gradients may also be specified.

Applied velocity conditions always refer to gridpoints. The velocities can be applied in terms of the x,y,z-global axes (i.e., with keywords **xvel**, **yvel** or **zvel**), or in terms of a local axes (with keywords **nvel**, **dvel** or **svel**). The local axes are defined by the normal vector at each gridpoint. The gridpoint normal direction is the average of the normal vectors of the faces meeting at the gridpoint. The d-s-n-axes at the gridpoint form a right-handed coordinate system (see Figure 3.25). At each gridpoint, all prescribed velocities must be on the same axes, either global axes or local axes.

Velocity conditions can be applied at any orientation by using the local axes. A normal gridpoint direction can be specified arbitrarily for the local axes by using the **plane** keyword; this will override the default normal direction. This feature is useful when specifying velocity conditions along corner boundaries. In the following example, it is required that velocities be applied, in the normal direction only, to each of two boundary planes.

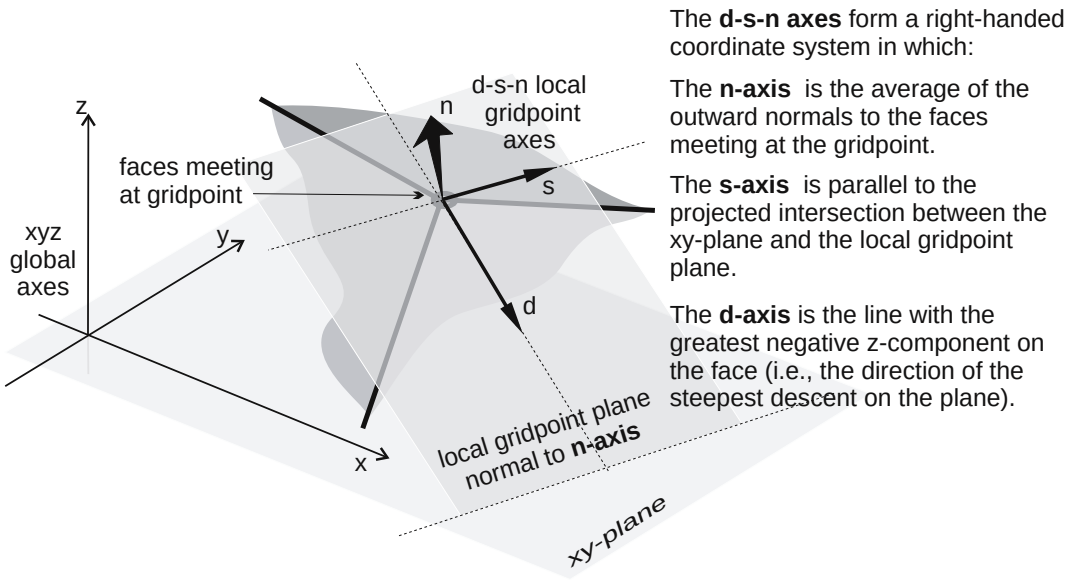

Figure 3.25 Local gridpoint axes defined by (d) dip direction, (s) strike direction and (n) normal direction

Example 3.19 Applying normal velocities at corners

```
gen zone brick size 4,4,4 p3 2,0,3.464
model elas
prop bulk 1e8 shear .3e8
macro left_boun  'plane dip 60 dd 270 origin 0.1,0,0 above'
macro right_boun 'plane dip 60 dd 270 origin 3.9,0,0 below'
apply nvel 0.1 plane dip 60 dd 270 range left_boun
apply nvel 0.1 plane dip 120 dd 90 range right_boun
; apply nvel 0.1 range left_boun
; apply nvel 0.1 range right_boun
step 1
plot grid vel
```

If the **plane dip 60 dd 270** keyword phrase and the **plane dip 120 dd 90** keyword phrase are removed from the **APPLY nvel** commands, then the velocities at the grid corners will not be applied in the desired directions. The default normal direction at the corner gridpoints is determined by all faces meeting at the gridpoint. (Compare Figure 3.26 to Figure 3.27.)

Applying different local axes at the same gridpoint is not permissible. This can require a variation in applied-velocity boundary conditions if the model is not oriented parallel with the x,y,z-coordinate axis. This is shown, for example, in the application of two roller boundary planes that intersect at the model edges. Example 3.20 illustrates the problem.

Example 3.20 Applying local axes velocities along model edges

```
gen zone brick size 4 4 4
model elastic
prop bulk 1e8 shear .3e8
apply nstress -1e6 range y 3.9 4.1
apply nvel 0.0 plane dip 90 dd 180 range y -.1 .1
apply nvel 0.0 plane dip 90 dd 270 range x -.1 .1
```

An error message will appear for the second **APPLY nvel** command, because the gridpoints along the model edge $x = 0$, $y = 0$ can only have one local coordinate system defined. The local coordinate systems must have the same **dip** and **dd** in order to avoid this problem. This problem can be overcome by using the same local axis system for both assign commands, and assigning the velocities in the strike direction in the first command and in the dip direction in the second command. Replace the two **APPLY nvel** commands with the following commands:

```
apply svel 0.0 plane dip 0 dd 0 range y -.1 .1
apply dvel 0.0 plane dip 0 dd 0 range x -.1 .1
```

The velocity boundary conditions are now correct along the model edge.

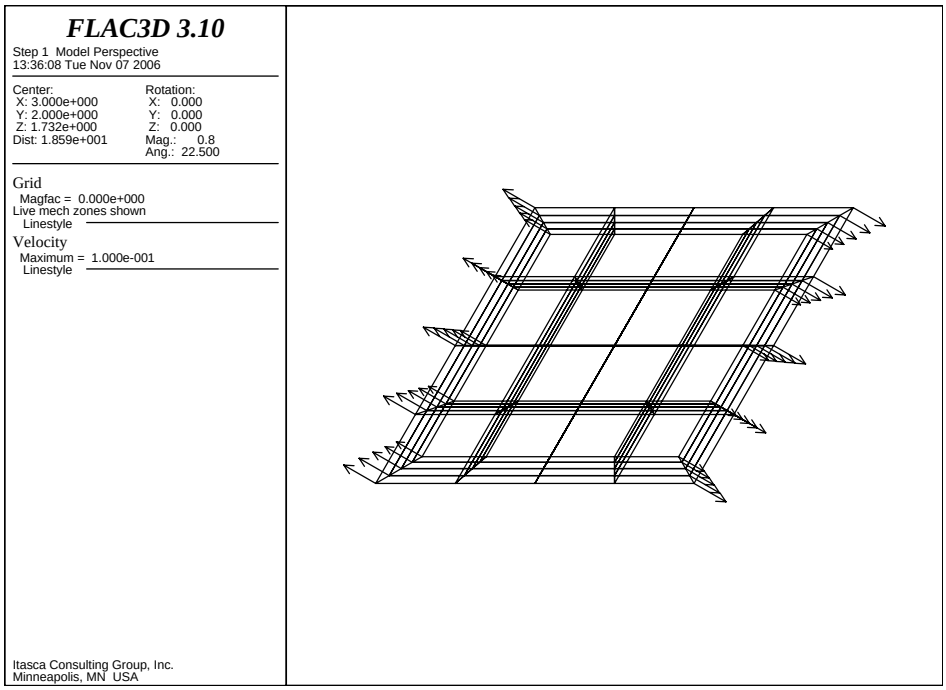

Figure 3.26 Applied velocities using the local axes plane

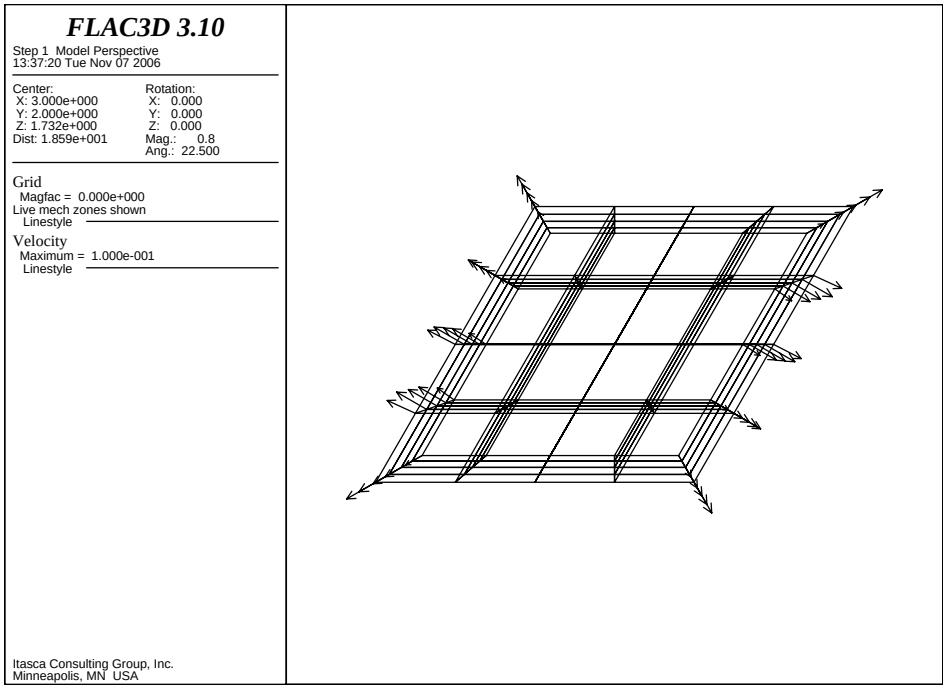

Figure 3.27 Applied velocities without the local axes plane

Local axes velocities cannot be applied to any gridpoints that are already **FIX**ed in any direction. Also, a global-axes velocity cannot be applied to a gridpoint with a **FIX**ed velocity in the same direction (i.e., **APPLY xvel** is not compatible with **FIX x**).

Alternatively, the **FIX** and **INI** commands can be used to fix the velocity in one or more of the x,y,z-directions at a gridpoint. During the calculation process, the velocity at the start of stepping is retained regardless of what forces act on the **FIX**ed gridpoints. If a zero displacement boundary is required later in a calculation, the appropriate gridpoint velocities can be set to zero before the gridpoints are **FIX**ed.

As an example, in order to simulate rigid movement of a rough platen on a test specimen, one of the following code snippets can be used:

```
fix x z range y -0.1 0.1
apply yvel = 1e-5 range y -0.1 0.1
```

or

```
fix x y z range y -0.1 0.1
ini yvel = 1e-5 range y -0.1 0.1
```

or

```
apply svel = 0 plane dip = 0 range y -0.1 0.1
apply dvel = 0 plane dip = 0 range y -0.1 0.1
apply nvel = 1e-5 plane dip = 0 range y -0.1 0.1
```

The **APPLY** command applies velocities at external or internal boundary gridpoints. The **APPLY** . . . **interior** command can be used to apply velocities to interior gridpoints. **FIX** and **INI** can operate on *any* gridpoints, boundary or interior.

When gridpoints are moved rigidly, the reaction forces at the gridpoints can be monitored using *FISH*. The sum of the reaction forces along a boundary may be obtained with a simple *FISH* function that adds up the *FISH* variables that correspond to **xforce**, **yforce** and/or **zforce** over the required range. (See Example 4.5.)

If nonuniform prescribed velocities are required, the **gradient** keyword may be used. For a more complicated velocity profile, or one that changes as the simulation proceeds, it will be necessary to write a *FISH* function. Example 3.21 demonstrates this for the model of a rotating retaining wall on the right-hand side of a block of soil.

Example 3.21 Rotating retaining wall

```
gen zone brick size 10 5 5
mod el
prop shear 1e8 bulk 2e8
fix x y z range x -.1 .1   y 0 5  z   0 5
fix x y z range x   0 10   y 0 5  z -.1 .1
fix x y z range x 9.9 10.1 y 0 5  z   0 5
table 1
def find_add
   head = null
   p_gp = gp_head
   loop while p_gp # null
      x_pos = gp_xpos(p_gp)
      if x_pos = width then
         new  = get_mem(2)
         mem(new)   = head
         mem(new+1) = p_gp
         head = new
      endif
      p_gp = gp_next(p_gp)
   endloop
end
set width=10.0
find_add
def apply_vel
   while_stepping
```

```
    ad = head
    loop while ad # null
       p_gp = mem(ad+1)
       gp_xvel(p_gp) =  vel_max * gp_zpos(p_gp) / height
       gp_zvel(p_gp) = -vel_max * (gp_xpos(p_gp) - width) / height
       ad = mem(ad)
    endloop
end
set large vel_max=1e-2  height=5.0
step 100
```

The gridpoints on the right boundary have their velocities adjusted at every timestep. The *FISH* function **find_add** is invoked before stepping, to store the addresses of the right boundary gridpoints in *FLAC3D*'s main memory, in order to avoid searching during the calculation. (See Section 2.5.5.2 in the ***FISH* volume** for further explanation on accessing memory directly.) Then, function **apply_vel** is called at every step to update the velocities of only those gridpoints whose addresses are stored. The velocity profile of the wall is adjusted as the geometry changes in large-strain mode. Note that the given velocity in this example is much too high for a realistic simulation; it is for demonstration purposes only.

3.3.3 Real Boundaries — Choosing the Right Type

It is sometimes difficult to know the type of boundary condition to apply to a particular surface of the body being modeled. For example, in modeling a laboratory triaxial test, should the load applied by the platen be regarded as a stress boundary, or should the platen be treated as a rigid displacement boundary? Of course, the whole testing machine, including the platen, could be modeled, but that might be very time-consuming. (Remember that *FLAC3D* takes a long time to converge if there is a large contrast in stiffnesses.) In general, if the object applying the load is very stiff compared with the sample (say, more than 20 times stiffer), then it may be treated as a rigid boundary. If it is soft compared with the sample (say, 20 times softer), then it may be modeled as a stress-controlled boundary. Clearly, a fluid pressure acting on the surface of a body is of the latter category. Footings on soil can often be represented as rigid boundaries that move with constant velocity for the purpose of finding the collapse load of the soil. This approach has another advantage — it is much easier to control the test and obtain a good load/displacement graph. It is well-known that stiff testing machines are more stable than soft testing machines.

3.3.4 Artificial Boundaries

Artificial boundaries fall into two categories: planes of symmetry and planes of truncation.

3.3.4.1 Symmetry Planes

Sometimes it is possible to take advantage of the fact that the geometry and loading in a system are symmetrical about one or more planes. For example, if everything is symmetrical about a vertical plane, then the horizontal displacements on that plane will be zero. Therefore, we can make that plane a boundary and fix all gridpoints in the horizontal direction using the **FIX** command (e.g., **FIX x**). If velocities on the plane of symmetry are not already zero, they should be set to zero with the **INI** command (e.g., **INI xvel = 0.0**). Both commands should have their range given as the boundary plane. In the case considered, the y- and z-components of velocity on the vertical plane of symmetry are not affected and should not be fixed. Similar considerations apply to other planes of symmetry. Planes of symmetry can also be set along boundaries that lie at angles to the x,y,z-coordinate axes. Use the command **APPLY nvel** = 0, for example. However, it will be necessary to also specify the **plane** keyword to correctly provide the symmetry plane for corner gridpoints (see Examples 3.19 and 3.20).

3.3.4.2 Boundary Truncation

When modeling infinite bodies (e.g., tunnels underground) or very large bodies, it may not be possible to cover the whole body with zones, due to constraints on memory and computer time. Artificial boundaries are placed sufficiently far away from the area of interest that the behavior in that area is not greatly affected. It helps to know how far away to place these boundaries, and what errors might be expected in the stresses and displacements computed for the area of interest.

Several points should be considered when selecting the location for artificial boundaries:

1. A fixed boundary causes both stresses and displacements to be underestimated, while a stress boundary does the opposite.

2. The two types of boundary condition “bracket” the true solution, so that it is possible to do two tests with small boundaries, and get a reasonable estimate of the true solution by averaging the two results.

3. The effect of boundary location is most noticeable for elastic bodies because the displacements and stress changes are more confined when plastic behavior is present; there is a natural cutoff distance within which most of the action occurs. The artificial boundary may be placed slightly farther away without serious error. However, any artificial boundary must not be sufficiently close that it attracts plastic flow and thereby invalidates the solution.

It is always best to run several (coarse) models first, with different boundary locations, to evaluate the potential influence of the boundary on the calculated response, before performing the detailed analysis. An example evaluation of this type is presented in the **Problem Solving** section of the two-dimensional *FLAC* **User’s Guide**.

3.4 Initial Conditions

In all civil or mining engineering projects, there is an in-situ state of stress in the ground, before any excavation or construction is started. In *FLAC3D*, an attempt is made to reproduce this in-situ state by setting initial conditions. Ideally, information about the initial state comes from field measurements but, when these are not available, the model can be run for a range of possible conditions. Although the range is potentially infinite, there are a number of constraining factors (e.g., the system must be in equilibrium, and the chosen yield criteria must not be violated anywhere).

In a uniform layer of soil or rock with a free surface, the vertical stresses are usually equal to $g\rho z$, where g is the gravitational acceleration, ρ is the mass density of the material, and z is the depth below the surface. However, the in-situ horizontal stresses are more difficult to estimate. There is a common — but erroneous — belief that there is some "natural" ratio between horizontal and vertical stress, given by $\nu/(1-\nu)$, where ν is the Poisson's ratio. This formula is derived from the assumption that gravity is suddenly applied to a mass of elastic material in which lateral movement is prevented. This condition hardly ever applies in practice, due to repeated tectonic movements, material failure, overburden removal and locked-in stresses due to faulting and localization (see Section 3.10.3). Of course, if we had enough knowledge of the history of a particular volume of material, we might simulate the whole process numerically to arrive at the initial conditions for our planned engineering works, but this approach is not often feasible. Typically, we compromise: a set of stresses is installed in the grid, and then *FLAC3D* is run until an equilibrium state is obtained. It is important to realize that there are an infinite number of equilibrium states for any given system.

In the following sections, we examine progressively more complicated situations and the ways in which the initial conditions may be specified. The user is encouraged to experiment with the various data files presented.

3.4.1 Uniform Stresses — No Gravity

For an excavation deep underground, the gravitational variation of stress from top to bottom of the excavation may be neglected because the variation is small in comparison with the magnitude of stress acting on the volume of rock to be modeled. The **SET gravity** command may be omitted, causing the gravitational acceleration to default to zero. The initial stresses are installed with the **INI** command — e.g.,

```
ini sxx=-5e6 syy=-1e7 szz=-5e6
```

The components σ_{11} (or σ_{xx}), σ_{22} (or σ_{yy}) and σ_{33} (or σ_{zz}) are set to compressive stresses of -5×10^6, -10^7 and -5×10^6, respectively, throughout the grid. Range parameters may be added if the stresses are to be restricted to a sub-grid. The **INI** command sets all stresses to the given values, but there is no guarantee that the stresses will be in equilibrium. There are at least two possible problems. First, the stresses may violate the yield criterion of a nonlinear model that has been assigned to the grid. In this case, plastic flow will occur immediately after the **STEP** command is given, and the stresses will readjust. This possibility should be checked by doing one trial step and examining the response (e.g., **PLOT block state**). Second, the prescribed stresses at the grid boundary may not equal the given initial stresses. In this case, the boundary gridpoints will start

to move as soon as a **STEP** command is given. Again, output should be checked (e.g., **PLOT vel**) for this possibility. Example 3.22 shows a set of commands that produce initial stresses that are in equilibrium with prescribed boundary stresses.

Example 3.22 Initial and boundary stresses in equilibrium

```
gen zone brick size 6 6 6
model elas
ini sxx=-5e6 syy=-1e7 szz=-2e7
apply sxx=-5e6 range x -0.1 0.1
apply sxx=-5e6 range x 5.9  6.1
apply syy=-1e7 range y -0.1 0.1
apply syy=-1e7 range y 5.9  6.1
apply szz=-2e7 range z -0.1 0.1
apply szz=-2e7 range z 5.9  6.1
```

Of course, if the boundary is **FIX**ed, rather than stress-controlled, the initial stresses will be in equilibrium automatically: the **APPLY** command is not necessary. See Section 3.3 for more details on boundary conditions and the **APPLY** command in particular.

3.4.2 Stresses with Gradients — Uniform Material

Near the ground surface, the variation in stress with depth cannot be ignored. The **SET grav** command is used to inform *FLAC3D* that gravitational acceleration operates on the grid. It is important to understand that the **SET grav** command does not directly cause stresses to appear in the grid; it simply causes *body forces* to act on all gridpoints. These body forces correspond to the weight of material surrounding each gridpoint. If no initial stresses are present, the forces will cause the material to move (during stepping) in the direction of the forces until equal and opposite forces are generated by zone stresses. Given the appropriate boundary conditions (e.g., fixed bottom, roller side boundaries), the model will, in fact, generate its own gravitational stresses that are compatible with the applied gravity. However, this process is inefficient, since many hundreds of steps may be necessary for equilibrium. It is better to initialize the internal stresses such that they satisfy both equilibrium and the gravitational gradient. The **grad** parameters on the **INI** command must be given so that the stress gradient matches the gravitational gradient, $g\rho$. The internal stresses must also match boundary stresses at stress boundaries. As mentioned in Section 3.3, there are several boundary conditions that could be used. Consider, for example, a 20 m $\times$ 20 m $\times$ 20 m box of homogeneous material at a depth of 200 m underground, with fixed base and stress boundaries on the other sides. The data file in Example 3.23 produces an equilibrium system.

Example 3.23 Initial stress state with gravitational gradient

```
gen zone brick size 10 10 10 p1 20,0,0 p2 0,20,0 p3 0,0,20
model mohr
prop bulk 5e9 shear 3e9 fric 35
```

```
ini density 2500
set gravity 0,0,-10
fix x y z range z -0.1 0.1
ini szz -5.0e6 grad 0,0,2.5e4
ini syy -2.5e6 grad 0,0,1.25e4
ini sxx -2.5e6 grad 0,0,1.25e4
apply szz -4.5e6 range z 19.9 20.1
apply szz -5.0e6 range z -0.1 0.1
apply sxx -2.5e6 grad 0,0,1.25e4 range x -0.1 0.1
apply sxx -2.5e6 grad 0,0,1.25e4 range x 19.9 20.1
apply syy -2.5e6 grad 0,0,1.25e4 range y -0.1 0.1
apply syy -2.5e6 grad 0,0,1.25e4 range y 19.9 20.1
```

In this example, horizontal stresses and gradients are equal to half the vertical stresses and gradients, but they may be set at any value that does not violate the yield criterion (Mohr-Coulomb, in this case). After preparing a data file such as in Example 3.23, one calculation step should be executed and the velocity field plotted; any failure to match internal stresses with boundary stresses will show up as a systematic movement at one or more boundaries. Small, chaotic velocities may be ignored — see Section 3.9.2. The unbalanced force after one step will be very small, but may not be exactly zero. This is a function of round-off error. Unbalanced force is calculated as a single-precision number, while applied forces are double-precision numbers.

It is worth noting that the gradient specified with the **grad** keyword associates stresses with zone centroids (i.e., the global location of the centroid determines the stress value from the gradient). Thus, although the applied σ_{zz}-stress varies from -5.0×10^6 to -4.5×10^6 in Example 3.23, the actual zone stresses in this example vary from -4.975×10^6 to -4.525×10^6. The stress-contour plot interpolates the zone stress from the centroid to the boundary; the stress at the boundary is *not* exactly the stress in the boundary zone. In order to plot the actual stresses in the zones, use the block-contour plot. This difference can be seen by comparing a plot using the command **PLOT contour szz** to one using the command **PLOT bcontour szz** for Example 3.23.

3.4.3 Stresses with Gradients — Nonuniform Material

It is more difficult to give the initial stresses when materials of different densities are present. Consider a layered system with a free surface, enclosed in a box with roller side boundaries and fixed base. Suppose that the material has the following density distribution:

1600 kg/m^3 from 0 to 10 m depth

2000 kg/m^3 from 10 to 15 m

2200 kg/m^3 from 15 to 25 m

An equilibrium state is produced by the data file in Example 3.24.

Example 3.24 Initial stress gradient in a nonuniform material

```
gen zone brick size 10 10 10 &
    p0 0,-25,0 p1 20,-25,0 p2 0,0,0 p3 0,-25,20
model elas
prop bulk 5e9 shear 3e9
ini density 1600 range y -10,0
ini density 2000 range y -15,-10
ini density 2200 range y -25,-15
set gravity 0,-10,0
fix x range x -.1 .1
fix x range x 19.9 20.1
fix z range z -.1 .1
fix z range z 19.9 20.1
fix y range y -25.1 -24.9
ini syy 0.0    grad 0,1.6e4,0 range y -10,0
ini syy 4e4    grad 0,2.0e4,0 range y -15,-10
ini syy 7e4    grad 0,2.2e4,0 range y -15,-25
```

The stress at each material interface must be calculated manually from the known overburden above it. This is used in the gradient formula (Eq. (3.1)) to calculate the value following **syy** on the **INI** command. The **grad** values are simply the variations across each layer due to the gravitational gradient. Note that the example is simplified — in a real case, the elastic moduli would vary, and there would be horizontal stresses. If high horizontal stresses exist in a layer, these may be installed with the **INI** command.

In a more complicated situation, it is best to use a *FISH* function to compute initial stress values from a known material property distribution.

3.4.4 Stress Initialization in a Nonuniform Grid

The existence of *internal* nonuniformities in a *FLAC3D* grid should not change the way in which stresses are initialized. However, some minor adjustment may be necessary, because forces do not balance exactly if the grid is irregular. For example, a grid may be distorted internally into the shape of a cylinder, with a view to "excavating" a tunnel at some later stage in the run. There will be a very slight initial imbalance in forces, but this may be relaxed with a few steps, as illustrated in Example 3.25.

Example 3.25 Initial stress state for a nonuniform grid

```
gen zone radcyl size 3 8 4 5 fill  p1 10,0,0 p2 0,10,0 p3 0,0,10
mode elastic
prop shear 3e8 bulk 5e8
fix x range x -.1 .1
fix x range x 9.9 10.1
```

```
fix y range y -.1 .1
fix y range y 9.9 10.1
fix z range z -.1 .1
ini szz = -2.5e5 grad 0,0,2.5e4
ini density 2500
set grav 0,0,-10
```

At one calculation step, an unbalanced force of approximately 8000 exists. This imbalance can be reduced by executing 250 steps. Now the unbalanced force is less than 100.

More complications arise when a free surface has an irregular geometry. Example 3.26 produces the "mountain range" shown in Figure 3.28. (The details of the generation process are not important in this context.)

Example 3.26 Initial stress state for an irregular free surface

```
gen zone brick size 15 15 10 p0 0,0,0 edge=100.0
model elastic
prop shear 3e8 bulk 5e8
def mountain
  gp = gp_head
  loop while gp # null
    zz = sqrt(gp_xpos(gp)^2 + gp_ypos(gp)^2)
    dz = 0.06 * sin(0.2 * zz + 100.0)      ; Sum Fourier terms for
    dz = dz + 0.06 * sin(0.22 * zz - 20.3) ; quasi-random surface
    dz = dz - 0.04 * sin(0.33 * zz + 33.3) ; topology.
    gp_zpos(gp) = 0.5 * gp_zpos(gp) * (1.0 + dz)
    gp = gp_next(gp)
  end_loop
end
mountain

fix x range x -.1 .1
fix x range x 99.9 100.1
fix y range y -.1 .1
fix y range y 99.9 100.1
fix z range z -.1 .1
set grav 0,0,-10
ini density=2000
ini szz=-2.0e6 (grad 0,0,2.0e4)
ini sxx=-4.0e6 (grad 0,0,4.0e4) syy=-4.0e6 (grad 0,0,4.0e4)
solve
```

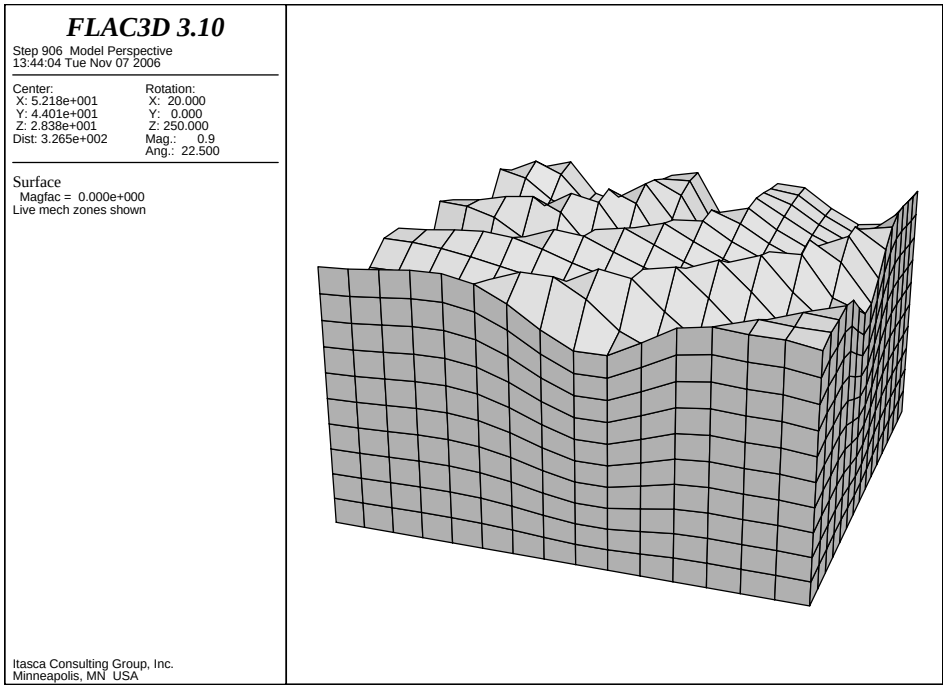

Figure 3.28 FLAC3D grid of mountain range

There is no simple way to deduce an equilibrium stress distribution for this grid: it must be modeled as a boundary-value problem. However, we may insert initial stresses in order to speed up the convergence and influence the final stress distribution. For example, if we know that there is a high horizontal in-situ stress, with only a small decrease in stress near the surface, we can initialize σ_{xx} and σ_{yy} to -2×10^5 at the approximate location of the surface, increasing to -4×10^6 at the bottom. The vertical stress σ_{zz} can be set to correspond to the average overburden.

The resulting horizontal stress distribution is shown in Figure 3.29. This represents just one of many ways to obtain an equilibrium solution; each one will produce a different, but physically valid, stress distribution. Several schemes are listed below.

1. Do not initialize stresses; allow gravity to compact the layer.
2. Initialize horizontal stress only, not vertical stress.
3. Impose constant stress at the lateral boundaries rather than zero horizontal displacement.
4. Remove irregular overburden from initial grid of uniform thickness.
5. Allow plastic flow to occur, thus removing stress concentrations.
6. Build up the profile layer by layer; equilibrate each layer.

There are probably many other possible schemes, particularly for a nonlinear, path-dependent material. No initial state is the "correct one" — the choice may depend on the type of geological process that is believed to have occurred in the field.

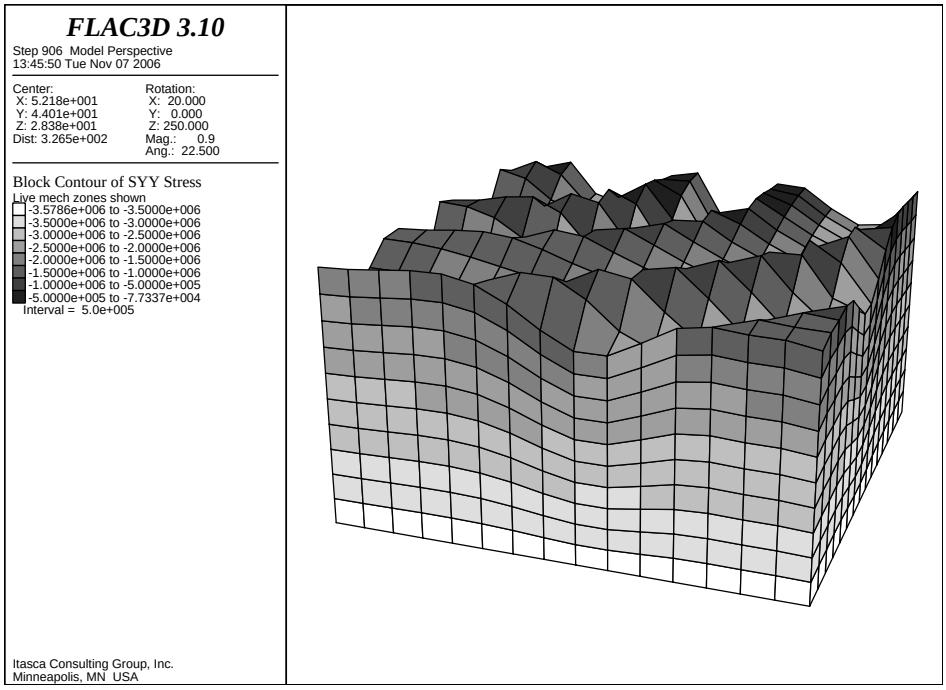

Figure 3.29 Horizontal stress contours in mountain range

3.4.5 Compaction within a Nonuniform Grid

Puzzling results are sometimes observed when a model is allowed to come to equilibrium under gravity, using a nonuniform grid. When a Mohr-Coulomb or other nonlinear constitutive model is used, the final stress state and displacement pattern are not uniform, even though the boundaries are straight and the free surface is flat. The data file in Example 3.27 illustrates the effect — see Figure 3.30 for the generated plot showing displacement vectors and vertical stress contours.

Example 3.27 Nonuniform stress initialized in nonuniform grid

```
gen zone brick  size 8 8 10 ratio 1.2 1 1
model mohr
ini dens 2000
prop bulk 2e8 shear 1e8
prop fric 30
fix x  range x -.1 .1
fix x  range x 7.9 8.1
```

```
fix y  range y -.1 .1
fix y  range y 7.9 8.1
fix z  range z -.1 .1
;ini szz -2.0e5 grad 0,0,2e4
;ini sxx -1.5e5 grad 0,0,1.5e4
;ini syy -1.5e5 grad 0,0,1.5e4
set grav 10
step 1000
;pause
;prop tens 1e10 coh 1e10
;step 750
;prop tens 0 coh 0
;step 250
```

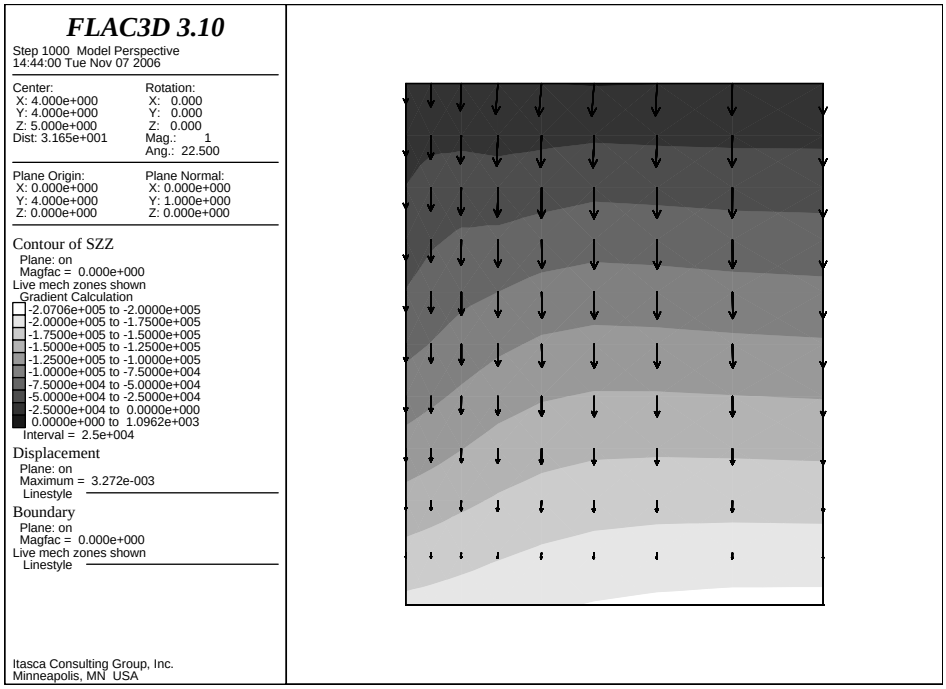

Figure 3.30 Nonuniform stresses and displacements

Since we have roller boundaries on the vertical sides, we might expect the material to move down equally on these sides. However, the grid is finer near the origin. *FLAC3D* tries to keep the local timestep equal for all zones, so it increases the inertial mass for the gridpoints near the $x = 0$ boundary to compensate for the smaller zone sizes. These gridpoints then accelerate more slowly than those near the $x = 8$ boundary. This will have no effect on the final state of a linear material, but it causes nonuniformity in a material that is path-dependent. For a Mohr-Coulomb material without cohesion, the situation is similar to dropping sand from some height into a container and expecting the final state to be uniform. In reality, a large amount of plastic flow would occur because the

confining stress does not build up immediately. Even with a uniform grid, this approach is not a good one because the horizontal stresses depend on the dynamics of the process.

The best solution is to use the **INITIAL** command to set initial stresses to conform to the desired K_0 value (ratio of horizontal to vertical stresses). For example, the **STEP 1000** command in the previous data file could be replaced by the lines

```
ini szz -2.0e5 grad 0,0,2e4
ini sxx -1.5e5 grad 0,0,1.5e4
ini syy -1.5e5 grad 0,0,1.5e4
```

A stable state is achieved with K_0 = 0.75; no stepping is necessary. (Invoke the **SOLVE** command to verify that the model is in equilibrium.)

If for some reason it is desirable to use *FLAC3D* to compute the final state, then the **STEP 1000** line could be replaced by the lines

```
prop tens 1e10 coh 1e10
step 750
prop tens 0 coh 0
step 250
```

Figure 3.31 shows the displacement vectors and vertical stress contours for this case. The material is prevented from yielding during the compaction process, but the original properties are restored when equilibrium is achieved.

The command **SOLVE elastic** automatically performs the same functions as the preceding commands: the mechanical calculation is first solved assuming high strength properties, and then solved using the actual strength properties. Presently, **SOLVE elastic** can only be applied for Mohr-Coulomb materials.

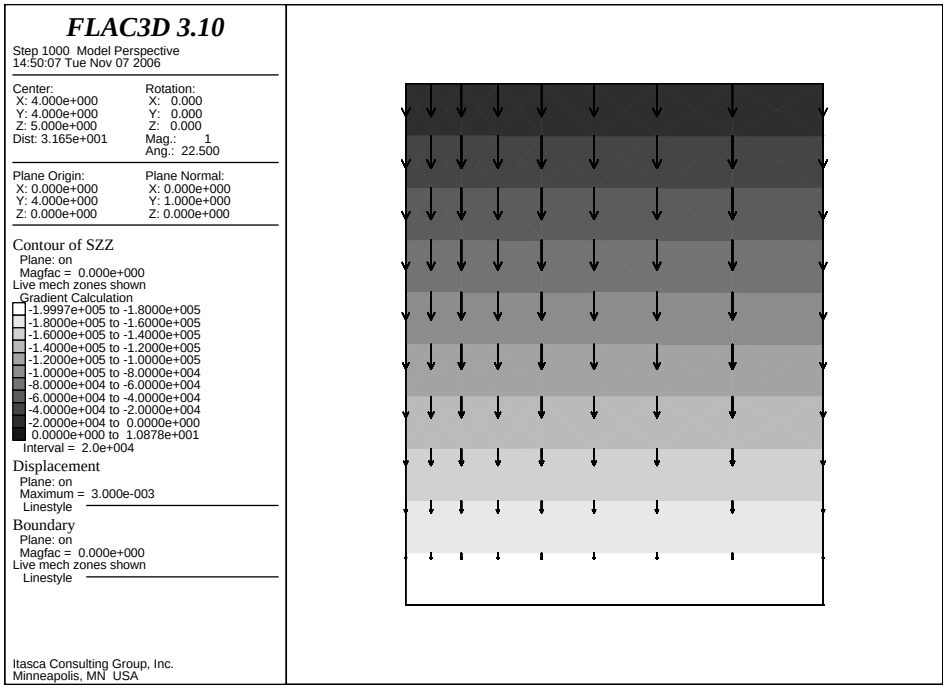

Figure 3.31 Uniform stresses and displacements

3.4.6 Initial Stresses following a Model Change

There may be situations in which one model is used in the process of reaching a desired stress distribution, but another model is used for the subsequent simulation. If one model is replaced by another non-null model, the stresses in the affected zones are preserved, as in Example 3.28.

Example 3.28 Initial stresses following a model change

```
gen zone brick size 5 5 5
model elas
prop sh 2e8 bu 3e8
fix x y z range  z -.1 .1
set grav 0 0 -10
ini dens 2000
solve
model mohr range x 0 2 y 0 5 z 0 2
prop sh 2e8 bu 3e8 fric 35 range x 0 2 y 0 5 z 0 2
```

At this point in the run, the stresses generated by the initial elastic model still exist and act as initial stresses for the region containing the new Mohr-Coulomb model.

Two points should be remembered. First, if a null model is installed in any zones (even if it is subsequently replaced by another model), all stresses are removed from the affected zones. Second, if one model is replaced by another and the stresses should physically be zero in the new model, then an **INI** command must be used to reset the stresses to zero. This situation would occur if rock is mined out and replaced by backfill; the backfill would have its own stress state, unrelated to the rock it is replacing.

3.4.7 Stress and Pore-Pressure Initialization with a Phreatic Surface

Pore pressures are initialized in the same way as stresses. However, the *gridpoint* pore pressures, rather than the *zone* pore pressures, are initialized, regardless of whether **CONFIG fluid** is specified.* Zone pore pressures are derived from gridpoint pore pressures by averaging. Zone pore pressures are then used to calculate effective stresses needed by the constitutive models.

Initialization of a partially saturated grid can be confusing; it may be easier to set the boundary conditions and let *FLAC3D* compute the phreatic surface and corresponding variations in stress gradients that occur because of differing zone densities. If pressures and stresses are to be initialized manually, often the procedure illustrated below can be used. The following example demonstrates the procedure for both the case of the grid configured for groundwater (**CONFIG fluid**) and the case not configured for groundwater.

Consider an impermeable box of height 10 m, which contains a solid, elastic material, fixed at the sides and base. Assume that only the bottom 5 m (z = 0 to 5 m) are fully saturated. The dry density of the solid is 2000 kg/m^3, and its porosity is 0.5. In the model for this example, we specify a grid with ten zones in the vertical direction.

It is best to work out the stress conditions for the zones from the top downward, based upon the different zone densities and the location of the phreatic surface. The influence of the fluid on zone density is calculated using the formula

$$\rho^{\mathrm{TOT}} = \rho^{\mathrm{DRY}} + n\, s\, \rho_w \tag{3.2}$$

where n is the porosity, s is the saturation, and ρ_w is the density of water.

For the specified zone size of 1 m, the saturation is zero from z = 6 m to z = 10 m. (Recall that saturation is a gridpoint variable.) Hence, the total density of each zone in this region is equal to the dry density of 2000 kg/m^3. The next row of zones (from z = 5 m to z = 6 m) has an *average* saturation of 0.5. Hence, the average density ρ^{TOT} is 2250 kg/m^3, using Eq. (3.2). For the zones in the region z = 0 to 5 m, the saturation is 1.0, so the total density is 2500 kg/m^3.

We calculate the total vertical stress gradient by adding the stresses due to the different zone densities. The change in vertical stress due to the density of 2000 kg/m^3 is applied with the command

---

* This differs from two-dimensional *FLAC*, in which gridpoint pore pressures are only initialized if **CONFIG gw** is specified.

```
ini szz -20e4  grad 0,0,20e3
```

An additional stress is added due to the zones between z = 5 m and 6 m with density of 2250 kg/m^3. This increment adds a stress gradient varying from zero at z = 6 m to -0.25×10^4 at z = 5 m. The increment remains constant at -0.25×10^4 from z = 5 m to z = 0.

```
ini szz add -1.5e4  grad 0,0,0.25e4  range z 5,6
ini szz add -0.25e4                  range z 0,5
```

The stress change is then added due to the zones between z = 5 m and z = 0 with density of 2500 kg/m^3. This increment adds a gradient varying from zero at z = 5 m to -2.5×10^4 at z = 0.

```
ini szz add -2.5e4  grad 0,0,0.5e4  range z 0,5
```

The grid pore pressure varies linearly from 5×10^4 at the base (z = 0), to zero at z = 5 m; above this, the material is unsaturated and the pore pressure is zero. We add the pore pressure with the command

```
ini pp 5.0e4   grad 0,0,-1.0e4  range z  0,5
```

The data file in Example 3.29 creates the initial conditions that are in equilibrium for this case (**CONFIG fluid**). Note that only the dry density of the material needs to be specified; the total densities will be calculated automatically.

Example 3.29 Stress and pore pressure initialization with a phreatic surface — grid configured for groundwater

```
config fluid
gen zone brick  size 8 5 10
model elas
model fl_iso
ini dens 2000
prop bulk 1e9 shear 5e8
prop poros 0.5 perm 1e-10
ini fmod 2e9
ini fdensity 1e3
ini sat 0
ini  sat 1 range z -.1 5.1
set grav 0 0 -10
fix x  range x -.1 .1
fix x  range x 7.9 8.1
fix y  range y -.1 .1
fix y  range y 4.9 5.1
fix z  range z -.1 .1
ini pp  5.e4        grad 0,0,-1.e4  range z 0.0 5.
ini szz -20e4       grad 0,0,20e3
ini szz add -1.5e4 grad 0,0,.25e4  range z 5,6
ini szz add -2.5e4 grad 0,0,.5e4   range z 0,5
```

```
ini szz add -.25e4                range z 0,5
solve
```

If the grid is not configured for groundwater, the different densities above and below the phreatic surface must be entered manually. The pore pressure gradient can be specified with either the **INI pp** or the **WATER table** command. The data file in Example 3.30 creates the initial conditions for the same example, but with the grid *not* configured for groundwater.

This example only illustrates the procedure for initializing vertical stresses. Horizontal stresses, in both the x- and y-directions, should also be initialized in a similar manner.

This procedure is admittedly complicated. If an error is made, then movement will start to occur from the first step, and fluid will flow. If further steps are taken, an equilibrium condition will be reached eventually, at the point at which densities, stresses and pressures are all compatible.

Example 3.30 Stress and pore pressure initialization with a phreatic surface — grid not configured for groundwater

```
gen zone brick  size 1 1 10

```

3.4.8 Initialization of Velocities

Until now, we have concentrated on initialization of stresses. Normally, the velocities *inside* the grid are not set explicitly: they default to zero initially. If, however, a velocity loading condition is specified at the boundary of a body, it is sometimes beneficial to initialize the velocities throughout the body to minimize the shock to the system. For example, in a simulated triaxial test with rigid platens, the velocities can be initialized to achieve an initial linear gradient throughout the sample, as shown in Example 3.31.

Example 3.31 Velocity gradient in a triaxial test

```
gen zone cyl p0 0 0 0 p1 1 0 0   p2 0 2 0  p3 0 0 1   size 4 5 4
gen zone reflect norm 1,0,0
gen zone reflect norm 0,0,1
model mohr
prop bulk 1.19e10 shear 1.1e10
prop coh 2.72e5 fric 44 ten 2e5
fix x y z range y -.1 .1
fix x y z range y 1.9 2.1
apply sxx =-1e5 szz=-1e5 range cyl end1 0,0,0 end2 0,2,0 radius 1
ini yvel 0 grad 0 -1e-4 0 range y 0 2
```

If the linear gradient is not applied, the internal gridpoints will receive an initial shock because they must accelerate to produce a negative velocity through the sample. The subsequent motion of the internal gridpoints is not controlled, since only the ends are fixed.

3.5 Loading and Sequential Modeling

By applying different model loading conditions at different stages of an analysis, it is possible to simulate changes in physical loading, such as sequences of excavation and construction. Changes in loading may be specified in a number of ways — e.g., by applying new stress or displacement boundaries, by changing the material model in zones to either a null material or to a different material model, or by changing material properties.

It is important to recognize that sequential modeling follows the stages of an engineering work — e.g., the stages in excavation and construction of a sheet pile wall. This modeling does *not*, however, include physical time as a parameter, and time-dependent behavior *cannot* be simulated.* Some engineering judgment must be used to estimate the effects of time. For example, a model parameter may be changed after a predetermined amount of displacement or strain has occurred. This displacement may be estimated to have occurred over a given period of time.

The following guidelines should be followed when performing loading changes or defining stages in a sequential analysis.

1. As discussed in Section 3.2, all zones must be defined initially, and those zones corresponding to future construction should be changed to null zones. Gridpoints must *not* be moved after solution stepping starts: displacements and stresses will not be adjusted to account for the change in element size or shape.

2. When material models are changed during a simulation sequence, all properties must be re-specified for the new model, even if the affected zones were previously assigned the same properties. Properties are lost when models are changed. Stresses in zones are preserved when models are changed, unless the zones are changed to null zones; in this case, all stresses in the affected zones are set to zero.

3. If the model is in equilibrium, a change in elastic properties will have no effect on the response of the model because elastic moduli are *tangent* moduli, not *secant* moduli. The model must be subjected to a change that causes unbalanced forces to develop. This may be caused, for example, by a change in strength properties if the current stresses exceed the new strength limit.

The recommended approach to sequential modeling is demonstrated by the following example. This problem involves the analysis of the loading on three tunnels (a service tunnel and two main tunnels) that are sequentially excavated and lined. The grid generation for this problem was described previously in Section 3.2.2.

---

* Of course, here we are referring to static mechanical processes. Transient calculations can be performed for groundwater flow and creep and thermal analyses with *FLAC3D*. Dynamic analysis can be performed with the dynamic option described in Section 3 in **Optional Features**.

The construction sequence to be analyzed consists of two modeling stages:

(1) excavation of the service tunnel; and

(2) installation of the liner for the service tunnel and excavation of the main tunnels.

The objective of the analysis is to investigate the influence of the main tunnel excavation on the response of the service tunnel.

The model is constructed to take advantage of symmetry in the problem. The service tunnel is located midway between the main tunnels, so a vertical plane of symmetry may be assumed to exist along the centerline of the service tunnel. The model grid is created in Example 3.32.

Example 3.32 Sequential excavation and lining of tunnels — initial grid

                        end2  0.0,50.0,-0.575736 rad 3.0
save tun0.sav
```

The resulting grid is shown in Figure 3.32. The grid is manipulated such that the invert of the service tunnel is at the same elevation as that of the main tunnel (see Section 3.2.2).

Note that this model, including the structural element liner added at stage 2, requires approximately 10 MB memory to create and run. However, the size of the save file is approximately 7 MB because the structural-element stiffness matrix is not saved, but is recomputed from the current saved state.

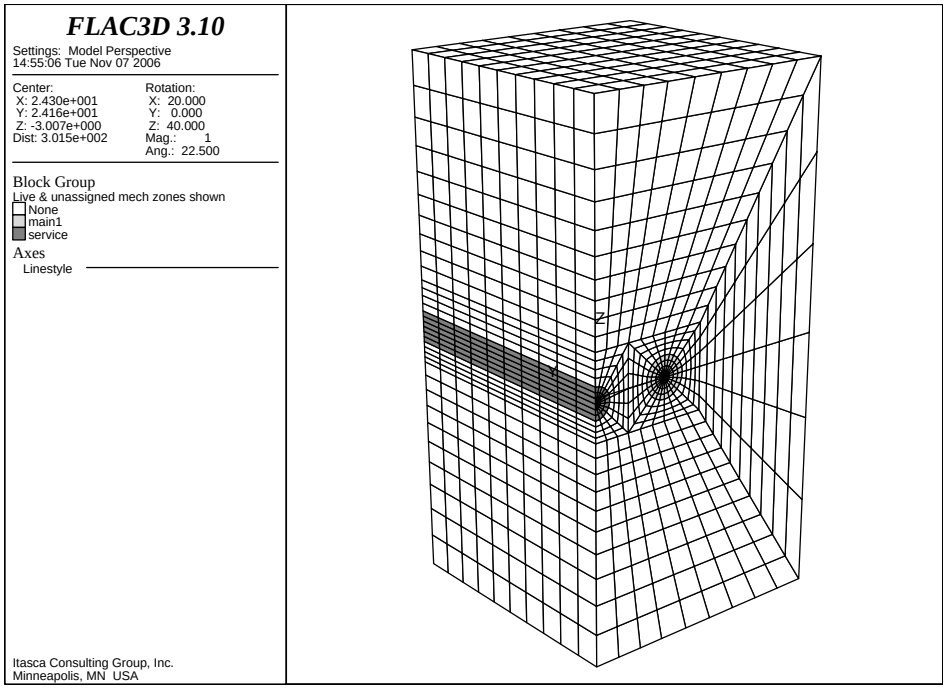

Figure 3.32 FLAC3D grid of main tunnels and service tunnel

A Mohr-Coulomb material model is initially defined for all zones. The plane of symmetry is specified, and an isotropic initial stress is assigned to the model. The model is in force equilibrium before an excavation is made. Note that only one calculational step is taken when the **SOLVE** command is issued, because the model is in equilibrium for the specified boundary and initial conditions. Example 3.33 lists the commands for this stage.

Example 3.33 Sequential excavation and lining of tunnels — initial state

hist gp zdis 0,25,2
solve
save tun1.sav
```

In the first stage, the solution is found with a 25 m section of the service tunnel excavated. The excavation is made instantaneously (with the command **MODEL null range group service y 0,25**).* This assumes that the actual excavation is done suddenly (e.g., by blasting). The resulting nonlinear response of the model will depend on the rate of unloading, so the modeler must decide whether this method of excavation in *FLAC3D* is appropriate to the physical problem. Alternatively, the excavation can be made by reducing the stresses along the excavation gradually. (For example, see Example 3.14.) The stage 1 commands are listed in Example 3.34.

Example 3.34 Sequential excavation and lining of tunnels — stage 1

```
; exacavate 25 m section of service tunnel
rest tun1.sav
model null range group service y 0,25
solve
save tun2.sav
```

The gridpoint history plots in Figure 3.33 for displacement at the springline and crown of the service tunnel indicate that the model has reached equilibrium within approximately 2300 calculation steps for stage 1.

---

* This approach is a simplistic simulation of the progressive advancement of the tunnel. For a more realistic model of sequential tunnel construction, see Section 4 in the **Examples volume**.

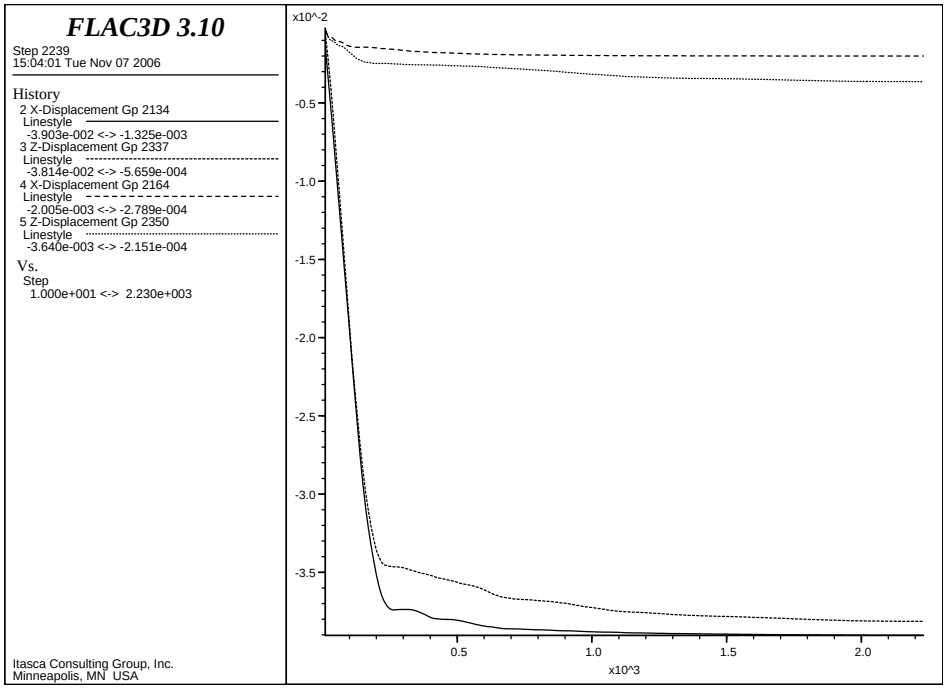

Figure 3.33 Displacement histories at crown and springline of service tunnel for stage 1 — Gp 2799 at (x=3, y=0, z=-1); Gp 2337 at (x=0, y=0, z=2); Gp 2812 at (x=3, y=25, z=-1); Gp 2350 at (x=0, y=25, z=2)

In the second stage, the lining is installed along the excavated section of the service tunnel. The lining is modeled using structural shell elements, and an elastic liner is assumed. Fixity conditions are specified for structural element nodes located on the symmetry plane of the grid to correspond to the same symmetry condition for the liner.

A 25 m section of the main tunnel is then excavated, and the solution is calculated for support provided by the lining (see Example 3.35).

```

We initialize the displacements in the model so that we can focus on the response due only to the excavation. The displacement histories at the two ends of the lined section of the service tunnel (i.e., at $y = 0$ and $y = 25$) indicate a nonsymmetric response of the service tunnel as a result of the partial excavation (see Figure 3.34). This is also evident in the contour plot of the displacement magnitude in the grid, and the minimum (i.e., major) principal stress (σ_1) in the lining (see Figure 3.35).

The modeling sequence may be repeated with different conditions of material properties, or locations of main tunnels relative to the service tunnel. If new tunnel locations are investigated, the grid must be regenerated and the model brought to an initial equilibrium state again. If different material properties are used, the model must be solved first for the response of the unlined service tunnel. Always remember that the model *must* be at an equilibrium state when the loading change is made.

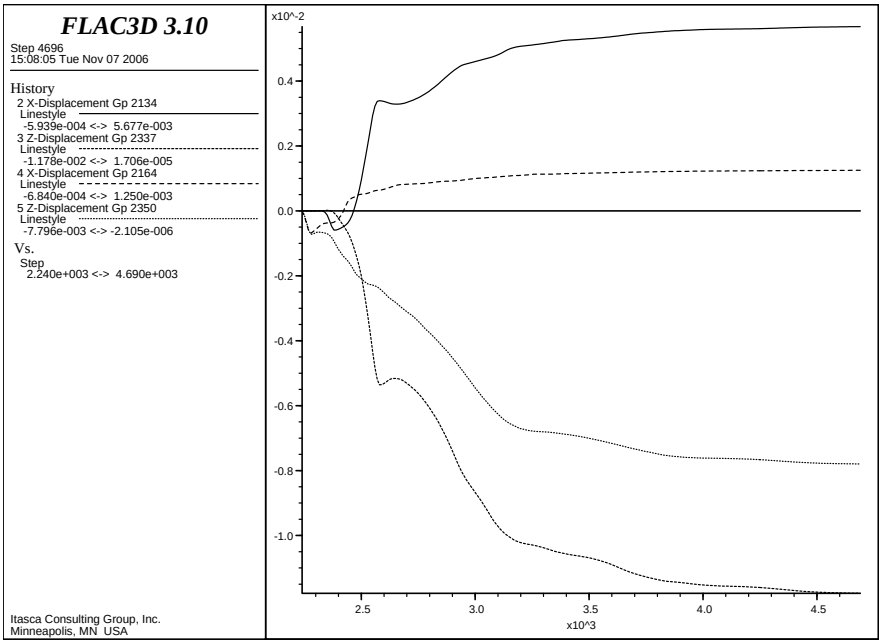

Figure 3.34 Displacement histories at crown and springline of service tunnel for stage 2 — Gp 2799 at (x=3, y=0, z=-1); Gp 2337 at (x=0, y=0, z=2); Gp 2812 at (x=3, y=25, z=-1); Gp 2350 at (x=0, y=25, z=2)

3.6 Choice of Constitutive Model

3.6.1 Overview of Constitutive Models

This section provides an overview of the constitutive models in *FLAC3D* and makes recommendations concerning their appropriate application. Section 2.1 in **Theory and Background** presents background information on the model formulations.

There are twelve built-in material models in *FLAC3D* :*

(1) null;

(2) elastic, isotropic;

(3) elastic, orthotropic;

(4) elastic, transversely isotropic;

(5) Drucker-Prager plasticity;

(6) Mohr-Coulomb plasticity;

(7) ubiquitous-joint plasticity;

(8) strain-hardening/softening Mohr-Coulomb plasticity;

(9) bilinear strain-hardening/softening ubiquitous-joint plasticity;

(10) double-yield plasticity;

(11) modified Cam-clay plasticity; and

(12) Hoek-Brown plasticity.

Each model is developed to represent a specific type of constitutive behavior commonly associated with geologic materials. The *null* model is used to represent material that is removed from the model. The *elastic, isotropic* model is valid for homogeneous, isotropic, continuous materials that exhibit linear stress-strain behavior. The *elastic, orthotropic* model and the *elastic, transversely isotropic* model are appropriate for elastic materials that exhibit well-defined elastic anisotropy. The *Drucker-Prager plasticity* model is a simple failure criterion in which the shear yield stress is a function of isotropic stress. The *Mohr-Coulomb plasticity* model is used for materials that yield when subjected

---

* These models are provided as *dynamic-linked libraries* (DLLs) that are loaded when *FLAC3D* is first executed. Users can modify the built-in models or create their own constitutive models as DLLs by following the procedures given in Section 4 in **Optional Features**. Also available are eight optional models that simulate viscoelastic and viscoplastic, time-dependent (creep) behavior (see Section 2 in **Optional Features**), and two optional models to simulate dynamic pore-pressure generation (see Section 3 in **Optional Features**).

to shear loading, but the yield stress depends on the major and minor principal stresses only; the intermediate principal stress has no effect on yield. The *ubiquitous-joint* model corresponds to a Mohr-Coulomb material that exhibits a well-defined strength anisotropy due to embedded planes of weakness. The *strain-hardening/softening Mohr-Coulomb* model is based upon the Mohr-Coulomb model, but is appropriate for materials that show an increase or degradation in shear strength when loaded beyond the initial failure limit. The *bilinear strain-softening ubiquitous-joint* model is a generalization of the ubiquitous-joint model that allows the strength properties for the matrix and the joint to harden or soften. The *double-yield* model is an extension of the strain-softening model to simulate irreversible compaction as well as shear yielding. The *modified Cam-clay* model accounts for the influence of volume change on deformability and on resistance to failure. The *Hoek-Brown* model is an empirical relation that is a nonlinear failure surface representing the strength limit for isotropic intact rock and rock masses. This model also includes a plasticity flow rule that varies as a function of the confining stress level.

The material models in *FLAC3D* are primarily intended for applications related to geotechnical engineering — e.g., underground construction, mining, slope stability, foundations, earth and rock-fill dams. When selecting a constitutive model for a particular engineering analysis, the following two considerations should be kept in mind.

1. What are the known characteristics of the material being modeled?

2. What is the intended application of the model analysis?

Table 3.4 presents a summary of the *FLAC3D* models along with examples of representative materials and possible applications of the models. The Mohr-Coulomb model is the most applicable for general engineering studies. Also, Mohr-Coulomb parameters for cohesion and friction angle are usually available more often than other properties for geo-engineering materials. The ubiquitous-joint, strain-softening, bilinear strain-softening/ubiquitous-joint and double-yield plasticity models are actually variations of the Mohr-Coulomb model. These models will produce results identical to those for Mohr-Coulomb if the additional material parameters are set to high values. The Drucker-Prager model is a simpler failure criterion than Mohr-Coulomb, but it is not generally suitable for representing failure of geologic materials. It is provided mainly to allow comparison of *FLAC3D* to other numerical programs that have the Drucker-Prager model but not the Mohr-Coulomb model. Note that, at zero friction, the Mohr-Coulomb model degenerates to the Tresca model, while the Drucker-Prager model degenerates to the von Mises model.

The Drucker-Prager and Mohr-Coulomb models are the most computationally efficient plasticity models; the other plasticity models require increased memory and additional time for calculation. For example, plastic strain is not calculated directly in the Mohr-Coulomb model (see Section 2.5.2 in **Theory and Background**). If plastic strain is required, the strain-softening, bilinear ubiquitous-joint or double-yield model must be used. These three models are primarily intended for applications in which the post-failure response is important — e.g., yielding pillars, caving or backfilling studies.

Table 3.4 FLAC3D constitutive models

Model	Representative Material	Example Application
null	void	holes, excavations, regions in which material will be added at later stage
elastic	homogeneous, isotropic continuum; linear stress-strain behavior	manufactured materials (e.g., steel) loaded below strength limit; factor-of-safety calculation
orthotropic elastic	materials with three mutually perpendicular planes of elastic symmetry	columnar basalt loaded below strength limit
transversely isotropic elastic	thinly laminated material exhibiting elastic anisotropy (e.g., slate)	laminated materials loaded below strength limit
Drucker-Prager plasticity	limited application; soft clays with low friction	common model for comparison to implicit finite-element programs
Mohr-Coulomb plasticity	loose and cemented granular materials; soils, rock, concrete	general soil or rock mechanics (e.g., slope stability and underground excavation)
strain-hardening / softening Mohr-Coulomb	granular materials that exhibit nonlinear material hardening or softening	studies in post-failure (e.g., progressive collapse, yielding pillar, caving)
ubiquitous-joint	thinly laminated material exhibiting strength anisotropy (e.g., slate)	excavation in closely bedded strata
bilinear strain-hardening/softening ubiquitous-joint	laminated materials that exhibit nonlinear material hardening or softening	studies in post-failure of laminated materials
double-yield	lightly cemented granular material in which pressure causes permanent volume decrease	hydraulically placed backfill
modified Cam-clay	materials for which deformability and shear strength are a function of volume change	geotechnical construction on clay
Hoek-Brown plasticity	isotropic rock material	geotechnical construction in rock

The tensile failure criterion is identical in the Drucker-Prager, Mohr-Coulomb, ubiquitous-joint, strain-softening, bilinear strain-softening/ubiquitous-joint and double-yield models. This criterion defines a tensile strength separately from the shear strength, and an associated flow rule for the onset of tensile failure. For the Drucker-Prager, Mohr-Coulomb and ubiquitous-joint models, the value assigned to the tensile strength remains constant when tensile failure occurs. Tensile softening can be modeled with the strain-softening, bilinear strain-softening ubiquitous-joint and double-yield models. (See Section 3.7.4.) Note that no record is made of notional voids that may open after tensile failure and tensile strain; if the strain rate becomes compressive, all models start to take compressive load immediately.

The double-yield and modified Cam-clay models both take into account the influence of volumetric change on material deformability and failure characteristics. In both models, tangential bulk and shear moduli are functions of plastic volumetric deformation.

The differences between the two models are summarized as follows.

In the Cam-clay model:

1. The elastic deformation is nonlinear, with the elastic moduli depending on mean stress.
2. Shear failure is affected by the occurrence of plastic volumetric deformation: the material can harden or soften depending on the degree of preconsolidation.
3. As shear loading increases, the material evolves toward a critical state at which unlimited shear strain occurs with no accompanying change in specific volume or stress.
4. There is no resistance to tensile mean stress.

In the double-yield model:

1. Elastic moduli remain constant during elastic loading and unloading.
2. Shear and tensile failure are not coupled to plastic volumetric change, due to volumetric yielding. The shear yield function corresponds to the Mohr-Coulomb criterion, and the tensile yield is evaluated based on a tensile strength.
3. Material hardening or softening, upon shear or tensile failure, is defined by tables relating friction angle and cohesion to plastic shear strain, and tensile strength to plastic tensile strain.
4. Volumetric yielding occurs; the isotropic stress at which yield occurs (*the cap pressure*) is not influenced by the amount of shear or tensile plastic deformation, but it increases (or hardens) with volumetric plastic strain.
5. A tensile strength limit and tensile softening can be defined.

The double-yield model was initially developed to represent the behavior of mine backfill material, for which preconsolidation pressures are low. The modified Cam-clay model is more applicable to soils such as soft clays for which preconsolidation pressures can have a significant effect on material behavior.

The Hoek-Brown model combines the generalized Hoek-Brown criterion with a plasticity flow rule that varies as a function of the confining stress level. At low confining stress, the volumetric expansion at yield is high, associated with axial splitting and wedging effects. At high confining stress, the material approaches a non-dilatant condition.

3.6.2 Selection of an Appropriate Model

A problem analysis should always start with the simplest material model; in most cases, an elastic model should be used first. This model runs the fastest and only requires two material parameters: bulk modulus and shear modulus (see Section 3.7). The model provides a simple perspective of stress-deformation behavior in the *FLAC3D* grid, and can define locations where stress concentrations may develop. This may assist the definition of zoning density for the grid.

It is often helpful to run a simple test of the selected material model before using it to solve the full-scale, boundary-value problem. This can provide insight into the expected response of the model compared to the known response of the physical material.

The following example illustrates the use of a simple test model. The problem application is the analysis of yielding mine pillars. A simple model is created to evaluate the implementation of the Mohr-Coulomb model versus the strain-softening model. This test also illustrates the effect of the selected measurement location on the reported results. The model is a compression test performed on a cylindrical grid composed of Mohr-Coulomb material.

Example 3.36 Compression test on Mohr-Coulomb material

```
gen zone cyl p0 0 0 0 p1 1 0 0   p2 0 2 0  p3 0 0 1   size 4 5 4

;ini pp 1e5
hist gp ydisp 0,0,0
hist zone syy 0,1,0
hist zone syy 1,1,0
step 3000
```

The axial (*y*-direction) stress-displacement response is monitored at the center and outer boundary in the grid. The results shown in Figure 3.36 are obtained from the command

```
plot his -2 -3 vs 1
```

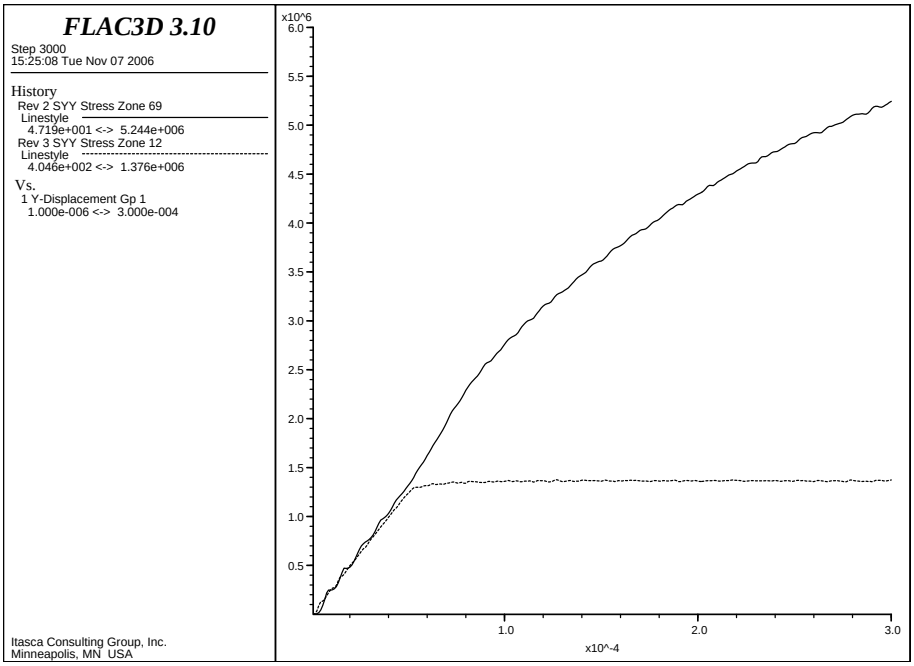

Figure 3.36 Stress-displacement plots for compression of Mohr-Coulomb material. Response is shown for an interior location (upper curve) and a boundary location (lower curve).

The test is now repeated with the strain-softening model:

Example 3.37 Compression test on strain-softening material

```
gen zone cyl p0 0 0 0 p1 1 0 0   p2 0 2 0  p3 0 0 1   size 4 5 4

ini yvel -1e-7 range y 1.9 2.1
hist gp ydisp 0,0,0
hist zone syy 0,1,0
hist zone syy 1,1,0
step 3000
```

The horizontal stress-displacement response is monitored again, as shown in Figure 3.37. This test produces distinct peak and residual failure stress levels.

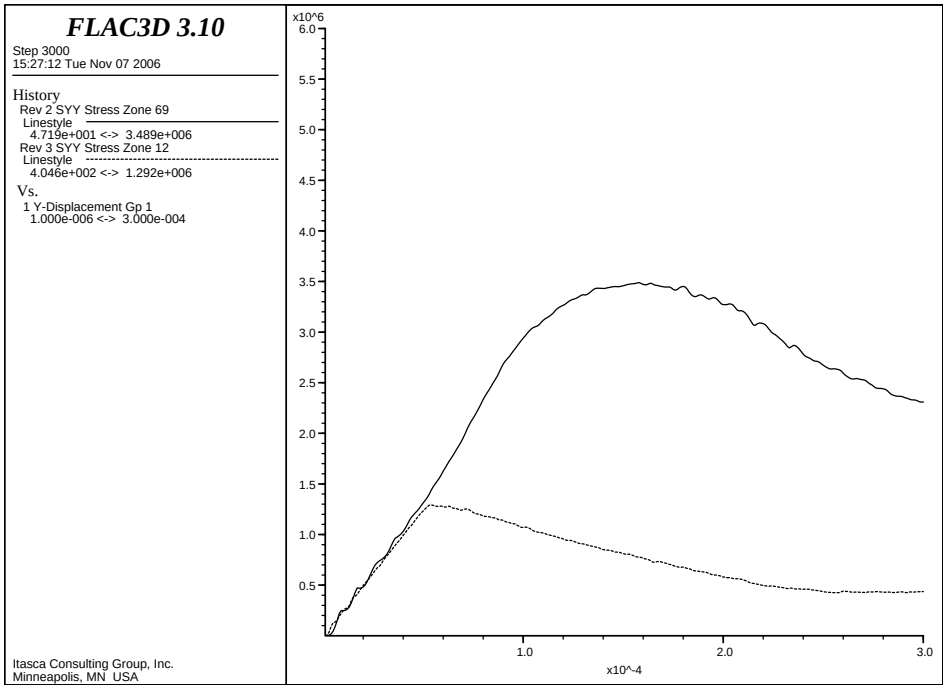

Figure 3.37 Stress-displacement for compression test of strain-softening material (similar monitoring points to Figure 3.36)

The strain-softening model assumes both a brittle softening (due to reduction in cohesion) and a gradual softening (due to a reduction in friction angle). The selection of the properties is discussed further in Section 3.7.

Comparison of Figures 3.36 and 3.37 illustrates the different responses of the two models. The initial response up to the onset of failure is identical, but post-failure behavior is quite different. Clearly, more data is required to use the strain-softening model and, typically, the softening model must be calibrated for each specific problem.

The effect of confinement on the “measured” response is also demonstrated from these plots. The history recorded in the middle of the grid shows that a higher stress level develops in the center of the model than at the free side. The location of monitoring points should correspond as closely as possible to the location of measurements in the physical problem.

3.6.3 The Effect of Water

Geologic materials generally appear weaker when the pore spaces contain a pore fluid under pressure. This is represented in *FLAC3D* by the incorporation of an effective stress that accounts for the presence of pore pressure in a zone. The pore pressures in *FLAC3D* are taken to be positive in compression. Thus, the effective stress σ' is related to the total stress σ and pore pressure p by

$$\sigma' = \sigma + p \tag{3.3}$$

Effective stresses are used in all of the plasticity models.

The effect of water can be seen by repeating Example 3.36 with constant pore pressure in the zones (i.e., an undrained compression test). Add the command

```
ini pp 1e5
```

to Example 3.36 before stepping. The lower strength is seen by comparing Figure 3.38 to Figure 3.36.

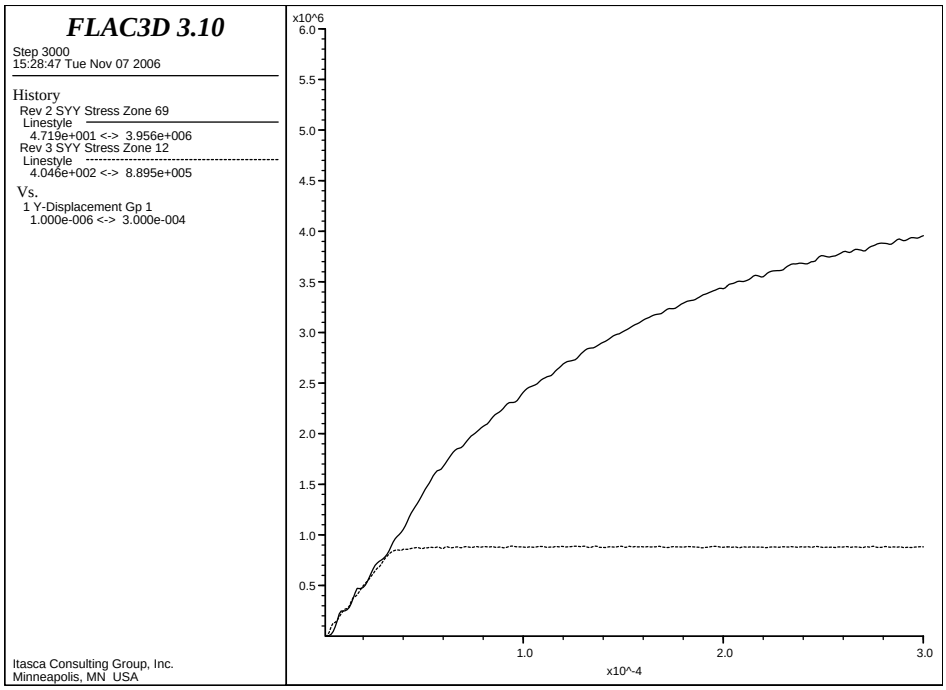

Figure 3.38 Stress-displacement plots for compression test of Mohr-Coulomb material at constant pore pressure

3.6.4 Ways to Implement Constitutive Models

There are several different ways in which a constitutive model can be implemented in *FLAC3D*. The standard way is to invoke one of the built-in models with the **MODEL** command. The user-defined models described in Section 4 in **Optional Features** are also invoked with the **MODEL** command.

As discussed in Section 3.6.1, the built-in models are provided as DLLs that are loaded when *FLAC3D* is first executed. The individual DLL files are contained in the "\FLAC3D310" directory with the executable code. The source codes for the built-in models are included in the "\Shared\Models\Source" sub-directory. These files should be reviewed as examples for users who wish to write and implement their own models. User-defined models are written in C++ and are implemented as DLLs that are loaded with the *FLAC3D* executable file in the same manner as the built-in models.* (See Section 4 in **Optional Features**.)

Often, it is desirable to modify an existing constitutive model (either a built-in model or a user-defined model) to make material properties dependent on other model parameters. There are three ways this can be done:

1. change properties of the built-in model via a *FISH* function that scans all the zones and is called at a specified step increment (say, every ten steps);
2. change properties in a user-defined constitutive model function at every step by reference to a formula; and
3. change properties via look-up tables (with the **TABLE** command) that modify strength properties as a function of plastic strain for the built-in strain-softening and double-yield models.

The third approach is the most efficient way to change properties in a *FLAC3D* model. The first approach is the least efficient.

---

* Note that this approach differs from the *FISH* constitutive model used in two-dimensional *FLAC*. With the DLL approach, user-defined models run at the same calculational speed as built-in models.

3.7 Material Properties

The material properties required in *FLAC3D* are generally categorized in one of two groups: elastic deformability properties and strength properties. This section provides an overview of the deformability and strength properties, and presents guidelines for selecting the appropriate properties for a given model. Additionally, there are special considerations such as the definition of post-failure properties, the extrapolation of laboratory-measured properties to the field scale, the spatial variation of properties and randomness of the property distribution, and the dependence of properties on confinement and strain. These topics are also discussed.

The selection of properties is often the most difficult element in the generation of a model because of the high uncertainty in the property database. When performing an analysis, especially in geomechanics, keep in mind that the problem will always involve a data-limited system – the field data will never be known completely. However, with the appropriate selection of properties based upon the available database, important insight to the physical problem can still be gained. This approach to modeling is discussed further in Section 3.10.

Material properties are conventionally derived from laboratory testing programs. The following sections describe intrinsic (laboratory-scale) properties and list common values for various rocks and soils.

3.7.1 Mass Density

The mass density is only required in a *FLAC3D* model if loading due to gravity is specified. The mass density is used to calculate the gravitational stresses within the model. Mass density has the units of mass divided by volume, and does *not* include the gravitational acceleration. Often in the literature, the *unit weight* of a material is given. If the unit weight is defined with units of force divided by volume, then this value must be divided by the gravitational acceleration before entering the value as *FLAC3D* input for density.

If a fluid-flow calculation is performed and *FLAC3D* is configured for fluid flow (**CONFIG fluid**), then the *dry* density of the solid material must be used. *FLAC3D* will compute the saturated density of each element using the known density of water and the porosity.

If not in **CONFIG fluid** mode, the saturated density should be used in elements below the phreatic surface. The following equation relates the total (saturated) density to the dry density:

$$\rho^{\mathrm{TOT}} = \rho^{\mathrm{DRY}} + n\, s\, \rho_w \tag{3.4}$$

where n is the porosity, s is the saturation and ρ_w is the density of water. s equals 1.0 if the element is fully saturated. The assignment of mass density for a partially saturated material is illustrated in Example 3.29 for a grid configured for fluid flow, and in Example 3.30 for a grid not configured for fluid flow.

3.7.2 Intrinsic Deformability Properties

Isotropic Elastic Properties — All material models in *FLAC3D*, except for the transversely isotropic elastic and orthotropic elastic models, assume an isotropic material behavior in the elastic range described by two elastic constants: bulk modulus (K) and shear modulus (G). The elastic constants K and G, rather than Young's modulus E, and Poisson's ratio ν, are used in *FLAC3D* because it is believed that bulk and shear moduli correspond to more fundamental aspects of material behavior than do Young's modulus and Poisson's ratio. (See note 13 in Section 3.8 for justification of using (K, G) rather than (E, ν).)

The equations to convert from (E, ν) to (K, G) are

$$K = \frac{E}{3(1-2\nu)}$$
$$G = \frac{E}{2(1+\nu)} \tag{3.5}$$

Eq. (3.5) should not be used blindly when ν is near 0.5, because the computed value of K will be unrealistically high and convergence to the solution will be very slow. It is better to fix the value of K at its known physical value (estimated from an isotropic compaction test or from the p-wave speed), and then compute G from K and ν.

Some typical values for elastic constants are summarized in Table 3.5 for selected rocks, and in Table 3.6 for selected soils.

Table 3.5 Selected elastic constants (laboratory-scale) for rocks (adapted from Goodman 1980)

	Dry Density (kg/m^3)	E (GPa)	ν	K (GPa)	G (GPa)
sandstone		19.3	0.38	26.8	7.0
siltstone		26.3	0.22	15.6	10.8
limestone	2090	28.5	0.29	22.6	11.1
shale	2210 - 2570	11.1	0.29	8.8	4.3
marble	2700	55.8	0.25	37.2	22.3
granite		73.8	0.22	43.9	30.2

Table 3.6 Selected elastic constants (laboratory-scale) for soils (adapted from Das 1994)

	Dry Density (kg/m^3)	Elastic Modulus E (MPa)	Poisson's Ratio
loose uniform sand	1470	10 - 26	0.2 - 0.4
dense uniform sand	1840	34 - 69	0.3 - 0.45
loose, angular-grained, silty sand	1630		
dense, angular-grained, silty sand	1940		0.2 - 0.4
stiff clay	1730	6 - 14	0.2 - 0.5
soft clay	1170 - 1490	2 - 3	0.15 - 0.25
loess	1380		
soft organic clay	610 - 820		
glacial till	2150		

Anisotropic Elastic Properties — For the special case of elastic anisotropy, the transversely isotropic, elastic model requires five elastic constants: E_1, E_3, ν_{12}, ν_{13} and G_{13}; and the orthotropic elastic model requires nine elastic constants: E_1, E_2, E_3, ν_{12}, ν_{13} ν_{23}, G_{12}, G_{13} and G_{23}. These constants are defined in Section 2.4.2 in **Theory and Background**.

Transversely isotropic elastic behavior is commonly associated with uniformly jointed or bedded rock. Several investigators have developed expressions for the elastic constants in terms of intrinsic isotropic elastic properties and joint stiffness and spacing parameters. A short summary of typical values for anisotropic rocks is given in Table 3.7.

Table 3.7 Selected elastic constants (laboratory-scale) for transversely isotropic rocks (Batugin and Nirenburg, 1972)

Rock	E_x (GPa)	E_y (GPa)	ν_{yx}	ν_{zx}	G_{xy} (GPa)
siltstone	43.0	40.0	0.28	0.17	17.0
sandstone	15.7	9.6	0.28	0.21	5.2
limestone	39.8	36.0	0.18	0.25	14.5
gray granite	66.8	49.5	0.17	0.21	25.3
marble	68.6	50.2	0.06	0.22	26.6
sandy shale	10.7	5.2	0.20	0.41	1.2

Fluid Elastic Properties — Models created for groundwater analysis also require the bulk modulus of the water, K_f, if the calculation involves incompressible grains, or the Biot modulus, M, if the grains are compressible. The physical value of K_f is 2 GPa for pure water at room temperature. The value selected should depend on the purpose of the analysis. If only steady-state flow or an initial pore pressure distribution is required (see Section 1.7 in **Fluid-Mechanical Interaction**), then as low a value of K_f as possible should be used, without compromising the physics. This is because the fluid timestep will be small for high K_f; also, the mechanical convergence will be very slow for high K_f. The fluid timestep, Δt_f, used by *FLAC3D* is related to porosity, n, permeability, k' and K_f:

$$\Delta t_f \propto \frac{n}{K_f k'} \tag{3.6}$$

We can determine the effect of changing K_f by deriving the coefficient of consolidation, C_v, for the case of a deformable fluid. (The fluid is assumed incompressible in most textbook solutions.)

$$C_v = \frac{k'}{m_v + \frac{n}{K_f}} \tag{3.7}$$

where

$$m_v = \frac{1}{K + 4G/3}$$

and

$$k = k' \gamma_f$$

where k' = permeability used in *FLAC3D*;
k = hydraulic conductivity in velocity units (e.g., m/sec); and
γ_f = the unit weight of water.

Since the consolidation time constant is directly proportional to C_v, the expression allows us to see how much error is introduced by reducing K_f from its real value (of 2×10^9 Pa).

The fluid bulk modulus will also affect the rate of convergence for a model with no flow, but with mechanical generation of pore pressure (see Section 1.7.5 in **Fluid-Mechanical Interaction**). If K_f is given a value comparable with the mechanical moduli, pore pressures will be generated as a result of mechanical deformations. If K_f is much greater than K, then convergence will be slow, but often it is possible to reduce K_f without significantly affecting the behavior. In real soils, for

example, pore water will contain some dissolved air, which substantially reduces its apparent bulk modulus.

In the case of no flow, the undrained saturated bulk modulus is

$$K_u = K + \frac{K_f}{n} \tag{3.8}$$

and the undrained Poisson's ratio is

$$\nu_u = \frac{3K_u - 2G}{2(3K_u + G)} \tag{3.9}$$

These values should be compared to the drained constants K and ν to evaluate the effect on the rate of convergence. It is important to remember that *drained* properties are used for coupled, mechanical fluid-flow calculations in *FLAC3D*.

For the case of compressible grains, the influence of Biot modulus, M, on the rate of convergence for a model is similar to that of fluid bulk modulus.

3.7.3 Intrinsic Strength Properties

The basic criterion for material failure in *FLAC3D* is the Mohr-Coulomb relation, which is a linear failure surface corresponding to shear failure:

$$f_s = \sigma_1 - \sigma_3 N_\phi + 2c\sqrt{N_\phi} \tag{3.10}$$

where $N_\phi = (1 + \sin\phi)/(1 - \sin\phi)$;
σ_1 = major principal stress (compressive stress is negative);
σ_3 = minor principal stress;
ϕ = friction angle; and
c = cohesion.

Shear yield is detected if $f_s < 0$. The two strength constants, ϕ and c, are conventionally derived from laboratory triaxial tests.

The Mohr-Coulomb criterion loses its physical validity when the normal stress becomes tensile but, for simplicity, the surface is extended into the tensile region to the point at which σ_3 equals the uniaxial tensile strength, σ^t. The minor principal stress can never exceed the tensile strength — i.e.,

$$f_t = \sigma_3 - \sigma^t \tag{3.11}$$

Tensile yield is detected if $f_t > 0$. Tensile strengths from rock and concrete are usually derived for a Brazilian test. Note that the tensile strength cannot exceed the value of σ_3, corresponding to the apex limit for the Mohr-Coulomb relation. This maximum value is given by

$$\sigma^t_{max} = \frac{c}{\tan\phi} \tag{3.12}$$

Typical values of cohesion, friction angle and tensile strength for a representative set of rock specimens are listed in Table 3.8. Cohesion and friction angle values for soil specimens are given in Table 3.9. Strength is often described in terms of the unconfined compressive strength, q_u. The relation between q_u and cohesion, c, and friction angle, ϕ, is given by

$$q_u = 2\ c\ \tan(45 + \phi/2) \tag{3.13}$$

Table 3.8 Selected strength properties (laboratory-scale) for rocks (adapted from Goodman 1980)

	Friction Angle (degrees)	Cohesion (MPa)	Tensile Strength (MPa)
Berea sandstone	27.8	27.2	1.17
Repetto siltstone	32.1	34.7	—
Muddy shale	14.4	38.4	—
Sioux quartzite	48.0	70.6	—
Indiana limestone	42.0	6.72	1.58
Stone Mountain granite	51.0	55.1	—
Nevada Test Site basalt	31.0	66.2	13.1

Table 3.9 Selected strength properties (drained, laboratory-scale) for soils (Ortiz et al., 1986)

	Cohesion	Friction Angle	
		Peak	Residual
	(kPa)	(degrees)	(degrees)
gravel	—	34	32
sandy gravel with few fines	—	35	32
sandy gravel with silty or clayey fines	1.0	35	32
mixture of gravel and sand with fines	3.0	28	22
uniform sand — fine	—	32	30
uniform sand — coarse	—	34	30
well-graded sand	—	33	32
low-plasticity silt	2.0	28	25
medium- to high-plasticity silt	3.0	25	22
low-plasticity clay	6.0	24	20
medium-plasticity clay	8.0	20	10
high-plasticity clay	10.0	17	6
organic silt or clay	7.0	20	15

Drucker-Prager strength parameters can be estimated from cohesion and friction angle properties. For example, assuming that the Drucker-Prager failure envelope circumscribes the Mohr-Coulomb envelope, the Drucker-Prager parameters q_ϕ and k_ϕ are related to ϕ and c by

$$q_\phi = \frac{6}{\sqrt{3}(3 - \sin\phi)} \sin\phi \tag{3.14}$$

$$k_\phi = \frac{6}{\sqrt{3}(3 - \sin\phi)} c \cos\phi \tag{3.15}$$

For further explanation on the relations between parameters, see Section 2.5.1.6 in **Theory and Background**.

The ubiquitous-joint model also requires strength properties for the planes of weakness. Joint properties are conventionally derived from laboratory testing (e.g., triaxial and direct shear tests).

These tests can produce physical properties for joint friction angle, cohesion, dilation angle and tensile strength.

Published strength properties for joints can be found, for example, in Jaeger and Cook (1969), Kulhawy (1975) and Barton (1976). Friction angles can vary from less than 10° for smooth joints in weak rock, such as tuff, to over 50° for rough joints in hard rock, such as granite. Joint cohesion can range from zero cohesion to values approaching the compressive strength of the surrounding rock.

It is important to recognize that joint properties measured in the laboratory typically are not representative of those for real joints in the field. Scale dependence of joint properties is a major question in rock mechanics. Often, comparison to similar joint properties derived from field tests is the only way to guide the choice of appropriate parameters. However, field test observations are extremely limited. Some results are reported by Kulhawy (1975).

3.7.4 Post-Failure Properties

In many instances, particularly in mining engineering, the response of a material after failure has initiated is an important factor in the engineering design. Consequently, the post-failure behavior must be simulated in the material model. In *FLAC3D*, this is accomplished with properties that define four types of post failure response:

(1) shear dilatancy;

(2) shear hardening/softening;

(3) volumetric hardening/softening; and

(4) tensile softening.

These properties are only activated after failure is initiated, as defined by the Mohr-Coulomb relation or the tensile-failure criterion. Shear dilatancy is simulated with the Mohr-Coulomb, ubiquitous-joint and strain-softening Mohr-Coulomb and ubiquitous-joint models. Shear hardening/softening is simulated with the strain-softening Mohr-Coulomb and ubiquitous-joint models, and volumetric hardening/softening is simulated with the modified Cam-clay model. Tensile softening is simulated with the strain-softening Mohr-Coulomb and ubiquitous-joint models.

3.7.4.1 Shear Dilatancy

Shear dilatancy, or dilatancy, is the change in volume that occurs with shear distortion of a material. Dilatancy is characterized by a dilation angle, ψ, which is related to the ratio of plastic volume change to plastic shear strain. This angle can be specified in the Mohr-Coulomb ubiquitous-joint and strain-hardening/softening models in *FLAC3D*. Dilation angle is typically determined from triaxial tests or shear-box tests. For example, the idealized relation for dilatancy, based upon the Mohr-Coulomb failure surface, is depicted for a triaxial test in Figure 3.39. The dilation angle is found from the plot of volumetric strain versus axial strain. Note that the initial slope for this plot

corresponds to the elastic regime, while the slope used to measure the dilation angle corresponds to the plastic regime.

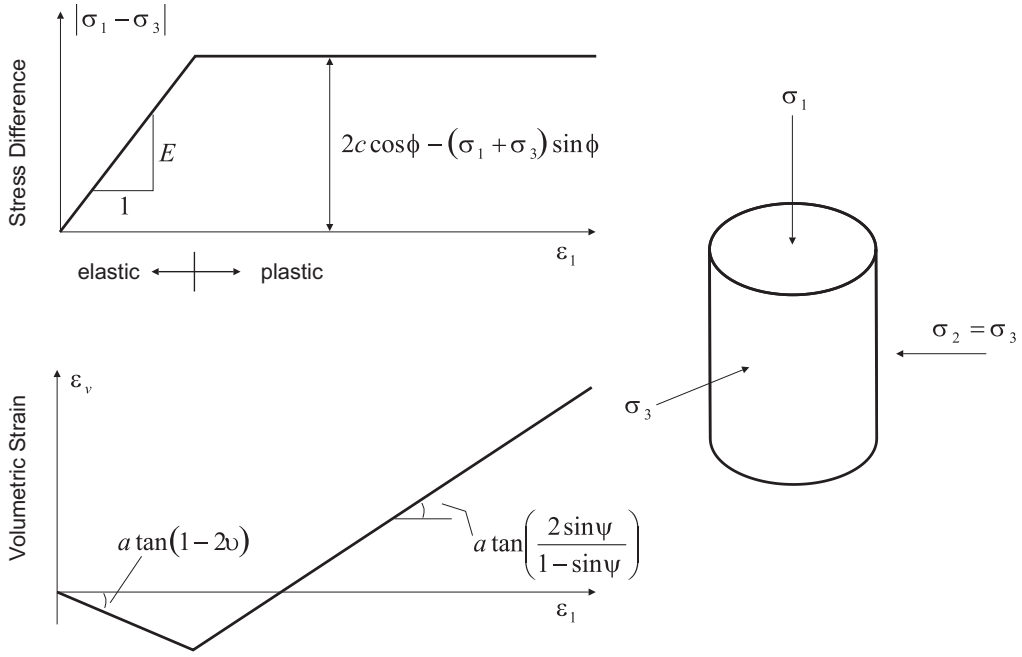

Figure 3.39 Idealized relation for dilation angle, ψ, from triaxial test results (Vermeer and de Borst, 1984)

For soils, rocks and concrete, the dilation angle is generally significantly smaller than the friction angle of the material. Vermeer and de Borst (1984) report the following typical values for ψ.

Table 3.10 Typical values for dilation angle (Vermeer and de Borst, 1984)

dense sand	15°
loose sand	$< 10°$
normally consolidated clay	0°
granulated and intact marble	$12° - 20°$
concrete	12°

Vermeer and de Borst observe that values for the dilation angle are approximately between 0° and 20°, whether the material is soil, rock or concrete. The default value for dilation angle is zero for all the constitutive models in *FLAC3D*.

Dilation angle can also be prescribed for the joints in the ubiquitous-joint model. This property is typically determined from direct shear tests, and common values can be found in the references discussed in Section 3.7.3.

3.7.4.2 Shear Hardening/Softening

The initiation of material hardening or softening is a gradual process once plastic yield begins. At failure, deformation becomes more and more inelastic as a result of micro-cracking in concrete and rock, and particle sliding in soil. This also leads to degradation of strength in these materials and the initiation of shear bands. These phenomena, related to localization, are discussed further in Section 3.10.

In *FLAC3D*, shear hardening and softening are simulated by making Mohr-Coulomb properties (cohesion and friction, along with dilation) functions of plastic strain (see Section 2.5.4 in **Theory and Background**). These functions are accessed from the strain-softening model, and can be specified either by using the **TABLE** command or via a *FISH* function.

Hardening and softening parameters must be calibrated for each specific analysis, and the values are generally back-calculated from results of laboratory triaxial tests. This is usually an iterative process. Investigators have developed expressions for hardening and softening. For example, Vermeer and de Borst (1984) propose the frictional hardening relation

$$\sin\phi_m = 2\frac{\sqrt{e_p\, e_f}}{e_p + e_f}\,\sin\phi \qquad \text{for } e_p \le e_f \tag{3.16}$$

$$\sin\phi_m = \sin\phi \qquad \text{for } e_p > e_f$$

where ϕ = ultimate friction angle;
ϕ_m = mobilized friction angle;
e_p = plastic strain; and
e_f = parameter.

Cundall (1989) incorporates this relation into two-dimensional *FLAC* to study localization in a frictional material. This is accomplished by approximating the function with a table relating friction angle to plastic strain (i.e., **TABLE** accessed from **PROP ftable**). This approach is demonstrated for the compression test described previously in Example 3.37.

Numerical testing conditions can influence the model response for shear hardening/softening behavior. The rate of loading can introduce inertial effects. The results are also grid-dependent. Thus, it is important to evaluate the model behavior for differing zone size and grid orientation whenever performing an analysis involving shear hardening or softening.

The following example, Example 3.38, illustrates the application of a shear-softening material in a uniaxial compression test. A low velocity is applied to the top and bottom of the specimen, and the grid contains fine zoning. The softening response is shown in the stress-displacement plot in

Figure 3.40. The development of localization and shear bands can be observed in Figures 3.41 and 3.42. The plastic region is identified as hourglass-shaped with spiral structures radiating from the hourglass cones.

3.7.4.3 Volumetric Hardening/Softening

Volumetric hardening corresponds to irreversible compaction; increasing the isotropic pressure can cause permanent volume decrease. This behavior is common in materials such as lightly cemented sands and gravels and over-consolidated clays.

Volumetric hardening/softening may be simulated in the double-yield model and the Cam-clay model. The double-yield model assumes that the hardening depends on plastic volume strain, while the Cam-clay model treats volumetric hardening as a function of both shear and volume strain.

The double-yield model takes its hardening rule from either a **TABLE** command or a *FISH* function. Section 2.3 in **Theory and Background** describes a recommended test procedure to develop these parameters from triaxial tests performed at constant mean stress, and for loading in which axial stress and confining pressure are kept equal. Typically, though, this data is not available. An alternative is to back-calculate the parameters from a uniaxial strain (or oedometer) test.

The modified Cam-clay model is defined by initial elastic moduli plus parameters that prescribe the nonlinear elasticity and hardening/softening behavior. The properties are:

κ	slope of the elastic swelling line
λ	slope of the normal consolidation line
M	material constant
p_c	preconsolidation pressure
p_1	reference pressure
v_0	initial specific volume
v_λ	specific volume at reference pressure on normal consolidation line

The definition of these properties can be found in soil mechanics texts (e.g., Wood 1990). The procedures for determining these properties from laboratory tests are described in Section 2.5.7.8 in **Theory and Background**. It is recommended that single-zone tests be conducted with *FLAC3D* to exercise the modified Cam-clay model, and verify whether the choice of model properties is adequate. An example test is provided in Section 2.5.7.9 in **Theory and Background**.

3.7.4.4 Tensile Softening

At the initiation of tensile failure, the tensile strength of a material will generally drop to zero. The rate at which the tensile strength drops, or tensile softening occurs, is controlled by the plastic tensile strain in *FLAC3D*. This function is accessed from the strain-softening model, and can be specified either by using the **TABLE** command or via a *FISH* function.

A simple tension test illustrates the tensile-softening behavior. The model is the same as that used previously in Examples 3.36 and 3.37. The ends of the cylindrical sample are now pulled apart at a constant velocity.

```

The plot of axial stress versus axial displacement (Figure 3.43) shows that the average axial stress through the center of the model drops to zero. (The stress will remain constant in the non-softening Mohr-Coulomb model.) The model decreases in diameter until tensile failure initiates, then expands as tensile softening occurs (see Figure 3.44). The brittleness of the tensile softening is controlled by the plastic tensile-strain function. As with the shear hardening/softening model, the tensile-softening model must be calibrated for each specific problem and grid size.

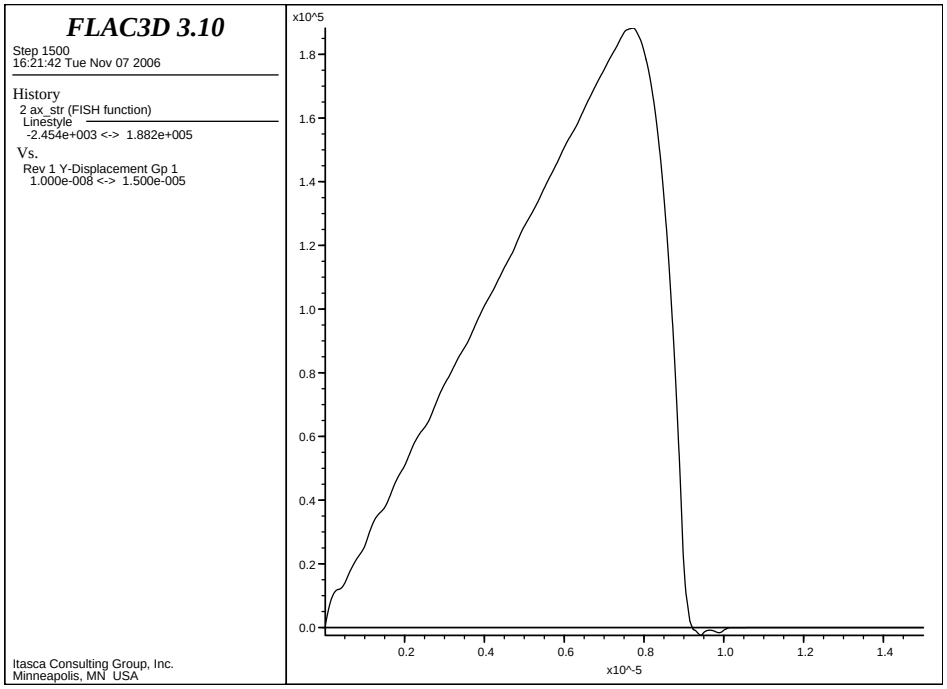

Figure 3.43 Axial stress versus axial displacement, for tensile test of tension-softening material

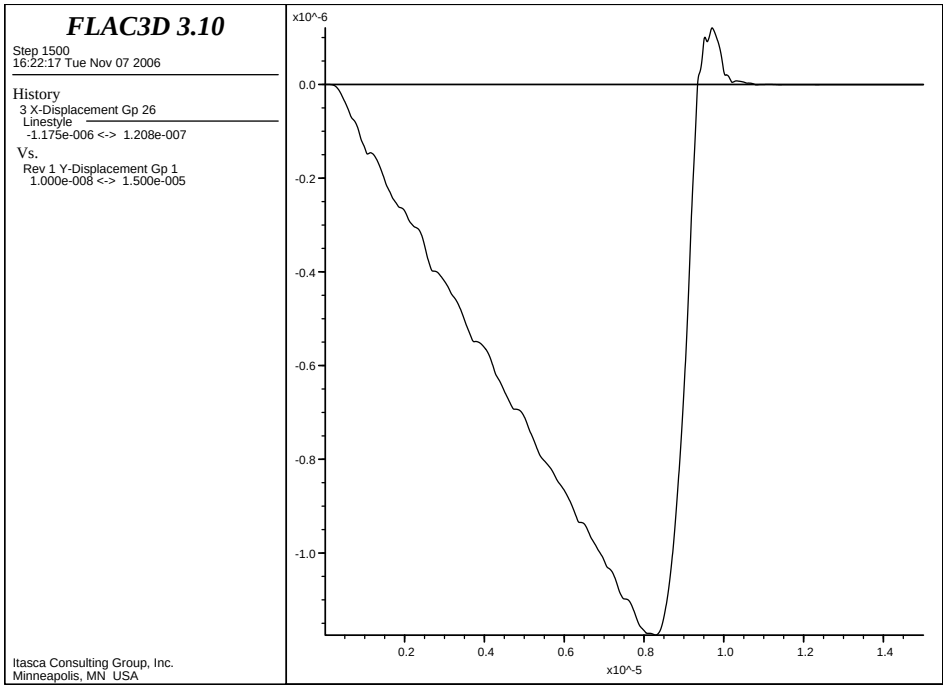

Figure 3.44 Circumferential displacement versus axial displacement, for tensile test of tension-softening material

3.7.4.5 Volume-Pressure Properties

The double-yield and modified Cam-clay models require material properties that relate pressure to volumetric change. For both models, the preconsolidation pressure is the maximum past consolidation pressure. In the double-yield model, the relation between pressure and volumetric change is expressed by a table relating the cap pressure to plastic volume strain. In the Cam-clay model, the pressure-volume relation is expressed by the slopes of the initial compression line and the reloading-unloading line for the plot of volumetric strain versus natural log of pressure. The recommended procedure for selecting volumetric properties for the double-yield model is given in Section 2.5.6.6 in **Theory and Background**, and in Section 2.5.7.8 in **Theory and Background**for the Cam-clay model.

3.7.5 Extrapolation to Field-Scale Properties

The material properties used in the *FLAC3D* model should correspond as closely as possible to the actual values of the physical problem. Particularly in rock, the laboratory-measured properties generally should not be used directly in a *FLAC3D* model for a full-scale problem. These properties should be scaled to account for the presence of discontinuities and heterogeneities present in a rock mass.

Several empirical approaches have been proposed to derive field-scale properties. Some of the more commonly accepted methods are discussed.

Deformability of a rock mass is generally defined by a modulus of deformation, E_m. If the rock mass contains a set of relatively parallel, continuous joints with uniform spacing, the value for E_m can be estimated by treating the rock mass as an equivalent transversely isotropic continuum. The following relation can then be used to estimate E_m in the direction normal to the joint set.

$$\frac{1}{E_m} = \frac{1}{E_r} + \frac{1}{k_n s} \tag{3.17}$$

where E_m = rock mass Young's modulus;

E_r = intact rock Young's modulus;

k_n = joint normal stiffness; and

s = joint spacing.

A similar expression can be derived for shear modulus:

$$\frac{1}{G_m} = \frac{1}{G_r} + \frac{1}{k_s s} \tag{3.18}$$

where G = rock mass shear modulus;

G_r = intact rock shear modulus; and

k_s = joint shear stiffness.

The equivalent continuum assumption, when extended to three orthogonal joint sets, produces the following relations:

$$E_i = \left(\frac{1}{E_r} + \frac{1}{s_i \, k_{ni}} \right)^{-1} \qquad (i = 1,\ 2,\ 3) \tag{3.19}$$

$$G_{ij} = \left(\frac{1}{G_r} + \frac{1}{s_i \, k_{si}} + \frac{1}{s_j \, k_{sj}} \right)^{-1} \qquad (i\ ,\ j = 1,\ 2,\ 3) \tag{3.20}$$

Several expressions have been derived for two- and three-dimensional characterizations and multiple joint sets. References for these derivations can be found in Singh (1973), Gerrard (1982a and b) and Fossum (1985).

In practice, the rock mass structure is often much too irregular, or sufficient data is not available, to use the preceding approach. It is common to determine E_m from a force-displacement curve obtained from an in-situ compression test. Such tests include plate-bearing tests, flatjack tests and dilatometer tests.

Bieniawski (1978) developed an empirical relation for E_m based upon field test results at sites throughout the world. The relation is based upon rock mass rating (RMR). For rocks with a rating higher than 55, the test data can be approximately fit to

$$E_m \ = \ 2(\text{RMR}) - 100 \tag{3.21}$$

The units of E_m are GPa.

For values of E_m between 1 and 10 GPa, Serafim and Pereira (1983) found a better fit, given by

$$E_m \ = \ 10^{\frac{\text{RMR}-10}{40}} \tag{3.22}$$

References by Goodman (1980) and Brady and Brown (1985) provide additional discussion on these methods.

The most commonly accepted approach to estimate rock mass strength is that proposed by Hoek and Brown (1980). The generalized Hoek-Brown failure criterion for jointed rock masses is defined by (Hoek and Brown, 1997):

$$\sigma_1' = \sigma_3' + \sigma_{ci}\left(m_b\frac{\sigma_3'}{\sigma_{ci}} + s\right)^a \tag{3.23}$$

where σ_1' and σ_3' are the maximum and minimum effective stress at failure, respectively (compressive stresses are positive), m_b is the value of the Hoek-Brown constant m for the rock mass, s and a are constants which depend upon the characteristics of the rock mass, and σ_{ci} is the uniaxial compressive strength of the intact rock pieces.

The tensile strength of the rock mass is estimated by Hoek and Brown (1997) to be

$$\sigma_{tm} = \frac{\sigma_{ci}}{2}\left(m_b - \sqrt{m_b^2 + 4s}\right) \tag{3.24}$$

Three properties are required in order to use the Hoek-Brown criteria (Eqs. (3.23) and 3.24):

1. the uniaxial compressive strength, σ_{ci}, of the intact rock pieces;
2. the Hoek-Brown constant, m_i, for the intact rock pieces; and
3. the value of the Geological Strength Index, GSI, for the rock mass. This provides an estimate for the Hoek-Brown constants, s, m_b and a.

For the intact rock pieces that compose the rock mass, Eq. (3.23) becomes

$$\sigma_1' = \sigma_3' + \sigma_{ci}\left(m_i\frac{\sigma_3'}{\sigma_{ci}} + 1\right)^{0.5} \tag{3.25}$$

The values for σ_{ci} and the constant m_i should be determined by statistical analysis of the results of a set of triaxial tests. The recommended procedure is given by Hoek and Brown (1997). This paper also presents estimates of σ_{ci} and m for preliminary design calculations when laboratory test results may not be available.

The Geological Strength Index (GSI) provides a system for estimating the reduction in rock mass strength. Two tables from Hoek and Brown (1997) can be used to estimate GSI (see Tables 3.11 and 3.12). Hoek and Brown (1997) then give the following relation between GSI and m_b, s and a.

$$m_b = m_i\, exp\left(\frac{GSI - 100}{28}\right) \tag{3.26}$$

For GSI > 25,

$$s = exp\left(\frac{GSI - 100}{9}\right)$$

and

$$a = 0.5 \tag{3.27}$$

For GSI < 25,

$$s = 0$$

and

$$a = 0.65 - \frac{GSI}{200} \tag{3.28}$$

Hoek and Brown (1997) also provide tables for these equations to facilitate their use.

It is possible to estimate Mohr-Coulomb friction angle and cohesion from the Hoek-Brown criterion (see, for example, Hoek 1990). For a given value of σ_3, a tangent to Eq. (3.23) will represent an equivalent Mohr-Coulomb yield criterion in the form

$$\sigma_1' = N_\phi \sigma_3' + \sigma_c^M \tag{3.29}$$

where $N_\phi = \frac{1+\sin\phi}{1-\sin\phi} = \tan^2(\frac{\phi}{2} + 45°)$.

By substitution, σ_c^M is

$$\sigma_c^M = \sigma_1 - \sigma_3 N_\phi = \sigma_3 + \sqrt{\sigma_3 \sigma_c m + \sigma_c^2 s} - \sigma_3 N_\phi = \sigma_3(1 - N_\phi) + \sqrt{\sigma_3 \sigma_c m + \sigma_c^2 s}$$

σ_c^M is the apparent uniaxial compressive strength of the rock mass for that value of σ_3.

The tangent to Eq. (3.23) is defined by

$$N_\phi(\sigma_3) = \frac{\partial \sigma_1}{\partial \sigma_3} = 1 + \frac{\sigma_c m}{2\sqrt{\sigma_3 \cdot \sigma_c m + s\sigma_c^2}} \tag{3.30}$$

The cohesion (c) and friction angle (ϕ) can then be obtained from N_ϕ and σ_c^M:

$$\phi = 2\tan^{-1}\sqrt{N_\phi} - 90^\circ \tag{3.31}$$

$$c = \frac{\sigma_c^M}{2\sqrt{N_\phi}} \tag{3.32}$$

Table 3.11 Characterization of rock masses on the basis of interlocking and joint alteration — from Hoek and Brown (1997)

ROCK MASS CHARACTERISTICS FOR STRENGTH ESTIMATES Based upon the appearance of the rock, choose the category that you think gives the best description of the 'average' undisturbed in situ conditions. Note that exposed rock faces that have been created by blasting may give a misleading impression of the quality of the underlying rock. Some adjustment for blast damage may be necessary and examination of diamond drill core or of faces created by pre-split or smooth blasting may be helpful in making these adjustments. It is also important to recognize that the Hoek-Brown criterion should only be applied to rock masses where the size of individual blocks is small compared with the size of the excavation under consideration.		SURFACE CONDITIONS					
		VERY GOOD Very rough, fresh unweathered surfaces	GOOD Rough, slightly weathered, iron stained surfaces	FAIR Smooth, moderately weathered or altered surfaces	POOR Slickensided, highly weathered surfaces with compact coatings or fillings of angular fragments	VERY POOR Slickensided, highly weathered surfaces with soft clay coatings or fillings
STRUCTURE		DECREASING SURFACE QUALITY ⇨				
	BLOCKY - very well interlocked undisturbed rock mass consisting of cubical blocks formed by three orthogonal discontinuity sets	B/VG	B/G	B/F	B/P	B/VP
	VERY BLOCKY - interlocked, partially disturbed rock mass with multifaceted angular blocks formed by four or more discontinuity sets	VB/VG	VB/G	VB/F	VB/P	VB/VP
	BLOCKY/DISTURBED- folded and/or faulted with angular blocks formed by many intersecting discontinuity sets	BD/VG	BD/G	BD/F	BD/P	BD/VP
	DISINTEGRATED - poorly interlocked, heavily broken rock mass with a mixture or angular and rounded rock pieces	D/VG	D/G	D/F	D/P	D/VP

3.7.6 Spatial Variation and Randomness of Property Distribution

Material properties can be specified to vary as a function of grid position. In fact, a different property can be assigned to every zone in a *FLAC3D* model, regardless of model size. The keyword **gradient** is available with the **PROPERTY** command to prescribe a linear variation of properties with position. For example, the following command provides a linear variation of cohesion in the x-direction.

```
prop coh 1e6 grad -1e5,0,0
```

An initial profile of a property can also be assigned via *FISH*.

With *FLAC3D*, it is also possible to study the influence of nonhomogeneity in a material. Any type of statistical property distribution can be introduced, since each element may have a unique property value. Two optional keywords are available with the **PROPERTY** command to apply a random distribution of a selected property. The keyword **gauss_dev** assumes a normal (Gaussian) distribution for the property, with a mean value, ***v***, and standard deviation, ***s***. The keyword **uniform_dev** assumes a uniform distribution with mean value, ***v***, and standard deviation, ***s***. Care should be taken to ensure that properties do not acquire negative values if ***s*** is large. As an example, the following command would give a mean friction angle of 40° with a standard deviation of ±5%.

```
prop friction 40 gauss_dev 2
```

3.8 Tips and Advice

When problem solving with *FLAC3D*, it is important to optimize the model for the most efficient analysis. This section provides several suggestions on ways to improve a model run. Also, some common pitfalls which should be avoided when preparing a *FLAC3D* calculation are listed.

1. **Check Model Runtime**

   The solution time for a *FLAC3D* run is proportional to $N^{4/3}$, where N is the number of zones. This formula holds for elastic problems solved for the equilibrium condition. The runtime will vary somewhat, but not substantially, for plasticity problems, and it may be much larger if continuing plastic flow occurs. It is important to check the speed of calculation on your computer for a specific model. An easy way to do this is to run the benchmark test described in Section 5.1. Then use this speed to estimate the speed of calculation for the specific model, based on interpolation from the number of zones.

2. **Effects on Runtime**

   FLAC3D will take longer to converge if:

   (a) there are large contrasts in stiffness in zone materials or between zones, structural members and interfaces; or

   (b) there are large contrasts in zone sizes.

   The code becomes less efficient as these contrasts become greater. The effect of a contrast in stiffness should be investigated before performing a detailed analysis. For example, a very stiff loading plate can be replaced by a series of fixed gridpoints that are given a constant velocity. (Remember that the **FIX** command fixes velocities, *not* displacements.) The inclusion of groundwater will act to increase the apparent mechanical bulk modulus — see Section 1 in **Fluid-Mechanical Interaction**.

3. **Considerations for Zoning Density**

   FLAC3D uses constant-strain elements. If the stress/strain gradient is high, you will need many zones to represent the varying distribution. Run the same problem with different zoning densities to check the effect. Constant-strain zones are used in *FLAC3D* because a better accuracy is achieved when modeling plastic flow with many low-order elements than with a few high-order elements. (See Section 1.2 in **Theory and Background** and the plasticity verification problems in the **Verifications volume**.)

   Try to keep the zoning as uniform as possible, particularly in the region of interest. Avoid long, thin zones with aspect ratios greater than 5:1, and avoid jumps in zone size (i.e., use smoothly graded grids). Make use of the **ratio** keyword with the **GENERATE** command to grade zone sizes smoothly from regions with fine zoning to regions with coarse zoning.

4. Automatic Detection of an Equilibrium State

By default, a mechanical force equilibrium is detected automatically when the **SOLVE** command is used. The equilibrium state is considered to be achieved when the ratio of the *maximum* unbalanced mechanical force magnitude for all the gridpoints in the model divided by the *average* applied mechanical force magnitude for all the gridpoints in the model drops below the value of 1×10^{-5}. Note that the applied force at a gridpoint results from both internal forces (e.g., due to gravitational loading) and external forces (e.g., due to an applied-stress boundary condition). This definition for unbalanced-to-applied force ratio provides an accurate limit for static equilibrium in most cases and, because the ratio is non-dimensional, the limiting value applies for models created with different systems of units.

Other definitions for the ratio are also provided; these can be applied with the **SET ratio** command. If the default ratio limit does not appear to provide a sufficiently accurate limit for static equilibrium, then the alternative ratio limits should be investigated.

The default ratio limit is also used to detect the steady-state solution for thermal and fluid-flow calculations. For thermal calculations, unbalanced and applied heat flux magnitudes, rather than unbalanced and applied mechanical forces, are evaluated. For fluid-flow calculations, the unbalanced and applied fluid flow magnitudes are evaluated.

5. Considerations for Selecting Damping

The default mechanical damping for static analysis is *local damping* (see Section 1.1.2.7 in **Theory and Background**), which is most efficient for removing kinetic energy when the velocity components of most gridpoints pass through zero periodically. This is because the mass-adjustment process depends on velocity sign changes. Local damping is a very efficient algorithm for achieving a static-equilibrium solution without introducing erroneous damping forces (see Cundall 1987).

If the problem involves significant regions of the grid having nonzero components of velocity at the final state of solution, then the default damping may be insufficient to reach an equilibrium state. A different form of damping, known as *combined damping*, provides better convergence to the steady-state than local damping for situations in which significant rigid-body motion of the grid is occurring. This may occur, for example, in a creep simulation or in the calculation of the ultimate capacity of an axially loaded pile. Use the command **SET mechanical damp combined** to invoke combined damping. Combined damping is not as efficient at removing kinetic energy, so care should be taken to minimize dynamic excitation of the system (see Example 3.14). It is possible to switch back to the default damping with the command **SET mechanical damp local**.

6. Check Model Response

FLAC3D shows how a similar physical system would behave. Make frequent simple tests to verify that you are actually doing what you think you are doing. For example, if a loading condition and geometry are symmetrical, make sure that the response is symmetrical. After making a change in the model, execute a few calculation steps (say, 5 or 10) to verify that the initial response is of the correct sign and in the correct location. Do back-of-the-envelope estimates of the expected order of magnitude of stress or displacements, and compare to the *FLAC3D* output.

If you apply a violent shock to the model, you will get a violent response. If you do nonphysically reasonable things to the model, you must expect strange results. If you get unexpected results at a given stage of an analysis, review the steps you followed up to that stage.

Critically examine the output before proceeding with the model simulation. If, for example, everything appears reasonable except for large velocities in one corner zone, do not go on until you understand the reason. In this case, you may not have fixed a boundary gridpoint properly.

7. Initializing Variables

It is common practice to initialize the displacements of the gridpoints between runs to aid in the interpretation of a simulation in which many different excavation stages are performed. This can be done because the code does not require the displacements in the calculation sequence — they are determined from the velocities of the gridpoints as a convenience to the user.

Initialization of the velocities, however, is a different matter. If the velocities of gridpoints are fixed at a constant value, they will continue to have this value until set otherwise. Therefore, do not initialize the velocities of the grid to zero simply to clear them — this will affect the simulation results. However, sometimes it is useful to set velocities to zero (for example, to remove all kinetic energy).

8. Minimizing Transient Effects on Static Analysis

For static analyses, transient waves can cause plastic models to follow poorly defined stress paths (unrealistic failure could be triggered). For this reason, it is often important to approach the solution (at each stage) gradually (i.e., make the solution more "static" by minimizing the effects of transient waves when problem conditions are changed suddenly.*

The recommended method to make a *FLAC3D* solution more static is to use a *FISH* function or table history to gradually reduce loads when material is removed (e.g., see examples in Section 3.3.1.2). When a sudden change is made (e.g., by nulling zones to simulate excavation), it is *not* advisable to set the strength properties to high values and step to equilibrium (and then reset the properties to realistic values). This latter method does not clearly define a direction in stress space to bring a zone within the yield surface (the entire process is non-physical).

9. Changing Material Models

FLAC3D does not have a limit on the number of different material models you may use during a simulation. The code has been dimensioned to allow the user to have a different material for each zone (if desired) for the maximum size grid for your version of *FLAC3D*.

10. Running Problems with In-situ Field Stresses and Gravity

There are a number of problems in which in-situ field stresses and gravity must be applied to the model. An example of such a problem is deep cut-and-fill mining, in which the rock mass is subjected to high in-situ stress fields (i.e., gravity stresses for the limited mesh size can be ignored), but in which the emplaced backfill pillars develop gravitational stresses that could collapse under the load. The important thing to note in these simulations (as in any simulation in which gravity is applied) is that at least three points on the grid must be fixed in space — otherwise, the entire grid will translate due to gravity. If you ever notice the entire grid translating in the direction of the gravitational acceleration vector, you have probably forgotten to fix the grid in space (e.g., see Example 3.18).

---

* This is not always the case. "Path-dependency" of a changing nonlinear system can be important. See the discussion in Section 3.10.3.

11. Determining Collapse Loads

In order to determine a collapse load, it often is better to use "strain-controlled" rather than "stress-controlled" boundary conditions — i.e., apply a constant velocity and measure the reaction forces, rather than apply forces and measure displacements. A system that collapses becomes difficult to control as the applied load approaches the collapse load. This is true of a real system as well as a model system.

12. Determining Factor of Safety

Factor of safety can be determined in *FLAC3D* for any selected parameter by taking the ratio of the calculated value under given conditions to that value which results in failure. For example,

$$F_w = \frac{\text{water level to cause collapse}}{\text{actual water level}}$$

$$F_L = \frac{\text{applied load to cause failure}}{\text{design load}}$$

$$F_\phi = \frac{\tan(\text{actual friction angle})}{\tan(\text{friction angle at failure})}$$

Note that the larger value is always divided by the smaller value (assuming that the system does not fail under the actual conditions). *The definition of failure must be established by the user.* A comparison of this approach based on strength reduction for determining factor of safety to that based upon limit analysis solutions is given by Dawson and Roth (1999) and Dawson et al. (1999). Also see Section 1 in the **Examples volume**.

The strength reduction method for determining factor of safety is implemented in *FLAC3D* through the **SOLVE fos** command. This command implements an automatic search for factor of safety using the bracketing approach, as described in Dawson et al. (1999). The **SOLVE fos** command may be given at any stage in a *FLAC3D* run, provided that all non-null zones contain the Mohr Coulomb model. During the solution process, properties will be changed, but the original state will be restored on completion, or if the **fos** search is terminated prematurely with the <Esc> key.

When *FLAC3D* is executing the **SOLVE fos** command, the bracketing values for F are printed continuously to the screen so that you can tell how the solution is progressing. If terminated by the <ESC> key, the solution process terminates, and the best current estimate of **fos** is displayed. A save file that corresponds

to the last non-equilibrium state is produced, so that velocity vectors, and so on, can be plotted. This allows a visualization of the failure mode.

Example 3.40, based upon an example stability analysis from Dawson et al. (1999), illustrates how the approach works. The run stops at $F = 1.06$. Figure 3.45 plots shear strain-rate contours and velocity vectors, which allow the failure surface to be identified.

It is recommended that the **SOLVE fos** command be given at an equilibrium state of a model (to improve solution time), but — as Example 3.40 demonstrates — this is not essential.

The procedure used by *FLAC3D* during execution of **SOLVE fos** is as follows. First, the code finds a "representative number of steps" (denoted by N_r), which characterizes the response time of the system. N_r is found by setting the

cohesion to a large value, making a large change to the internal stresses, and finding how many steps are necessary for the system to return to equilibrium. Then, for a given factor of safety, F, N_r steps are executed. If the unbalanced force ratio is less than 10^{-3}, then the system is in equilibrium. If the unbalanced force ratio is greater than 10^{-3}, then another N_r steps are executed, exiting the loop if the force ratio is less than 10^{-3}. The mean value of force ratio, averaged over the current span of N_r steps, is compared with the mean force ratio over the previous N_r steps. If the difference is less than 10%, the system is deemed to be in non-equilibrium, and the loop is exited with the new non-equilibrium, F. If the above-mentioned difference is greater than 10%, blocks of N_r steps are continued until: (1) the difference is less than 10%; or (2) 6 such blocks have been executed; or (3) the force ratio is less than 10^{-3}. The justification for case (1) is that the mean force ratio is converging to a steady value that is greater than that corresponding to equilibrium; the system must be in continuous motion. The *FISH* intrinsic variable **`fos_f`** allows access to the current value of F during **SOLVE fos** execution (see Section 2.5.1.1 in the ***FISH* volume**).

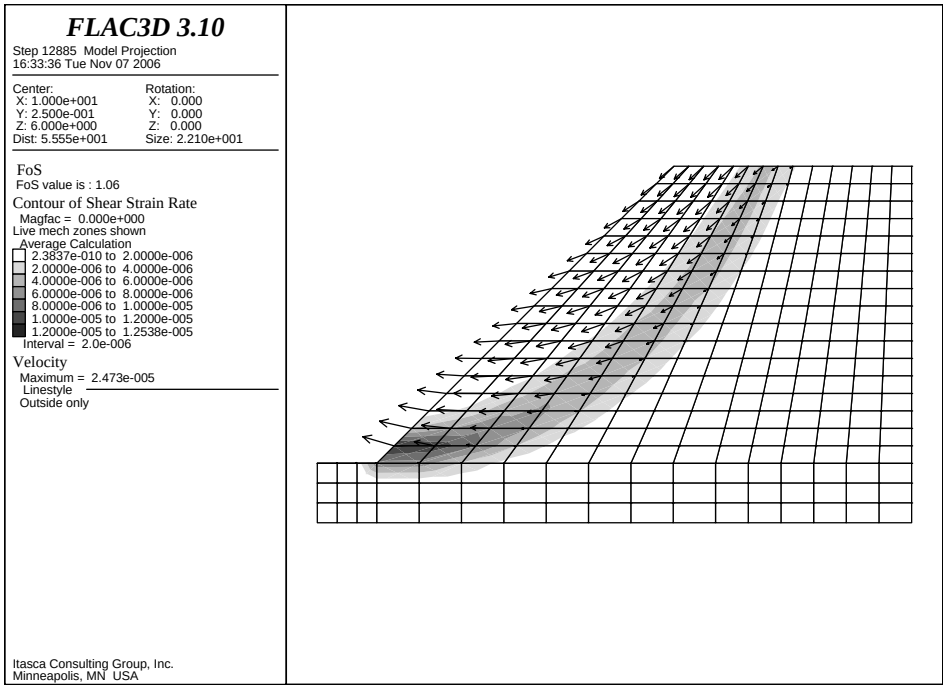

Figure 3.45 Shear strain-rate contours and velocity vectors in slope model at last non-equilibrium state

13. Use Bulk and Shear Moduli

It is better to use bulk modulus, K, and shear modulus, G, than Young's modulus, E, and Poisson's ratio, ν, for elastic properties in *FLAC3D*.

The pair (K, G) makes sense for all elastic materials that do not violate thermodynamic principles. The pair (E, ν) does not make sense for certain admissable materials. At one extreme, we have materials that resist volumetric change but not shear; at the other extreme, materials that resist shear but not volumetric change. The first type of material corresponds to finite K and zero G, and the second to zero K and finite G. However, the pair (E, ν) is not able to characterize either the first or the second type of material. If we exclude the two limiting cases (conventionally, $\nu = 0.5$ and $\nu = -1$), the equations

$$\begin{aligned} 3K(1-2\nu) &= E \\ 2G(1+\nu) &= E \end{aligned} \tag{3.33}$$

relate the two sets of constants. These equations hold, however close we approach (but not reach) the limiting cases. We do not need to relate them to physical tests that may or may not be feasible — the equations are simply the consequence of two possible ways of defining coefficients of proportionality. Suppose we have a material in which the resistance to distortion progressively reduces, but in which the resistance to volume change remains constant. ν approaches 0.5 in this case. The equation $3K(1-2\nu) = E$ must still be satisfied. There are two possibilities (argued on *algebraic*, not physical, grounds): either E remains finite (and nonzero) and K tends to an arbitrarily large value; or K remains finite and E tends to zero. We rule out the first possibility because there is a limiting compressibility to all known materials (e.g., 2 GPa for water, which has a Poisson's ratio of 0.5). This leaves the second, in which E is varying drastically, even though we supposed that the material's principal mode of elastic resistance was unchanging. We deduce that the parameters (E, ν) are inadequate to express the material behavior.

3.9 Interpretation

Since *FLAC3D* models a nonlinear system as it evolves in time, the interpretation of results may be more difficult than with a conventional finite-element program that produces a "solution" at the end of its calculation phase. There are several indicators that can be used to assess the state of the numerical model — e.g., whether the system is stable, unstable, or in steady-state plastic flow. The various indicators are described below.

3.9.1 Unbalanced Force

Each gridpoint is surrounded by up to eight zones that contribute forces to the gridpoint. At equilibrium, the algebraic sum of these forces is almost zero (i.e., the forces acting on one side of the gridpoint nearly balance those acting on the other). If the unbalanced forces approach a constant nonzero value, this indicates that failure and plastic flow are occurring within the model. During timestepping, the maximum unbalanced force is determined for the whole grid; this force is displayed continuously on the screen. It can also be saved as a history and viewed as a graph. The unbalanced force is important in assessing the state of the model, but its magnitude must be compared with the magnitude of typical internal forces acting in the grid. In other words, it is necessary to know what constitutes a "small" force. A representative internal gridpoint force may be found by multiplying stress by zone area perpendicular to the force, using values that are typical in the area of interest in the grid. Denoting R as the ratio of maximum unbalanced force to the representative internal force, expressed as a percentage, the value of R will never decrease to zero. However, a value of 1% or 0.1% may be acceptable as denoting equilibrium, depending on the degree of precision required (e.g., R = 1% may be good enough for an intermediate stage in a sequence of operations, while R = 0.1% may be used if a final stress or displacement distribution is required for inclusion in a report or paper). Note that a low value of R only indicates that forces balance at all gridpoints. However, steady plastic flow may be occurring without acceleration. In order to distinguish between this condition and "true" equilibrium, other indicators, such as those described below, should be examined.

3.9.2 Gridpoint Velocities

The grid velocities may be assessed either by plotting out the whole field of velocities (using the **PLOT vel** command) or by selecting certain key points in the grid and tracking their velocities with histories (**HIS gp xvel**, **yvel** or **zvel**). Both types of plots are useful. Steady-state conditions are indicated if the velocity histories show horizontal traces in their final stages. If they have all converged to near-zero (in comparison to their starting values), then absolute equilibrium has occurred; if a history has converged to a nonzero value, then steady plastic-flow is occurring at the gridpoint corresponding to that history. If one or more velocity history plots show fluctuating velocities, then the system is likely to be in a transient condition. Note that velocities are expressed in units of displacement divided by number of steps.

The plot of the field of velocity vectors is more difficult to interpret, since both the magnitudes and the nature of the pattern are important. As with gridpoint forces, velocities never decrease precisely to zero. The magnitude of velocity should be viewed in relation to the displacement that would

occur if a significant number of steps (e.g., 1000) were to be executed. For example, if current displacements in the system are of the order of 1 cm, and the maximum velocity in the velocity plot is 10^{-8} m/step, then 1000 steps would produce an additional displacement of 10^{-5} m, or 10^{-3} cm, which is 0.1% of the current displacements. In this case, it can be said that the system is in equilibrium even if the velocities all seem to be "flowing" in one direction. More often, the vectors appear to be random (or almost random) in direction and (possibly) in magnitude. This condition occurs when the changes in gridpoint force fall below the accuracy limit of the computer, which is around six decimal digits. A random velocity field of low amplitude is an infallible indicator of equilibrium and no plastic flow.

If the vectors in the velocity field are coherent (i.e., there is some systematic pattern) and their magnitude is quite large (using the criterion described above), then either plastic flow is occurring or the system is still adjusting elastically (e.g., damped elastic oscillation is taking place). To confirm that continuing plastic flow is occurring, a plot of plasticity indicators should be examined, as described below. If, however, the motion involves elastic oscillation, then the magnitude should be observed in order to indicate whether such movement is significant. Seemingly meaningful patterns of oscillation may be seen but, if amplitude is low, then the motion has no physical significance.

3.9.3 Plastic Indicators

For the plasticity models in *FLAC3D*, the command **PLOT block state** displays those zones in which the stresses satisfy the yield criterion. Such an indication usually denotes that plastic flow is occurring, but it is possible for an element simply to "sit" on the yield surface without any significant flow taking place. It is important to look at the whole pattern of plasticity indicators to see whether a *mechanism* has developed.

Two types of failure mechanisms are indicated by the plasticity state plot: shear failure and tensile failure — each type is designated by a different color on the plot.* The plot also indicates whether stresses within a zone are currently on the yield surface (i.e., the zone is at active failure now, **-n**), or the zone has failed earlier in the model run, but now the stresses fall below the yield surface (the zone has failed in the past, **-p**). Initial plastic flow can occur at the beginning of a simulation, but subsequent stress redistribution unloads the yielding elements so that their stresses no longer satisfy the yield criterion, indicated by **shear-p** or **tension-p** (on the plasticity state plot).

A failure mechanism is indicated if there is a contiguous line of active plastic zones (indicated by either **shear-n** or **tension-n**) that join two surfaces. The diagnosis is confirmed if the velocity plot also indicates motion corresponding to the same mechanism.

If there is no contiguous line or band of active plastic zones between boundaries, two patterns should be compared before and after the execution of, say, 500 steps. Is the region of active yield increasing or decreasing? If it is decreasing, then the system is probably heading for equilibrium; if it is increasing, then ultimate failure *may* be possible.

---

* For the ubiquitous-joint model, shear failure along the joint plane is designated by **u:shear** and tensile failure by **u:tension** on the plasticity plot.

If a condition of continuing plastic flow has been diagnosed, one further question should be asked — Does the active flow band(s) include zones adjacent to artificial boundaries? The term "artificial boundary" refers to a boundary that does not correspond to a physical entity, but one that exists simply to limit the size of the grid that is used (see Section 3.3.4). If plastic flow occurs along such a boundary, then the solution is not realistic, because the mechanism of failure is influenced by a nonphysical entity. This comment only applies to the final steady-state solution; intermediate stages may exhibit flow along boundaries.

3.9.4 Histories

In any problem, there are certain variables that are of particular interest — e.g., displacements may be of concern in one problem, but stresses may be of concern in another. Liberal use should be made of the **HIST** command to track these important variables in the regions of interest. After some timestepping has taken place, plots of these histories often provide a way to find out what the system is doing.

3.10 Modeling Methodology

3.10.1 Modeling of Data-Limited Systems

In a field such as geomechanics, where data is not always available, the methodology used in numerical modeling should be different from that used in a field such as mechanical engineering. Starfield and Cundall (1988) provide suggestions for an approach to modeling that is appropriate for a data-limited system. This paper should be consulted before any serious modeling with *FLAC3D* is attempted. In essence, the approach recognizes that field data (such as in-situ stresses, material properties and geological features) will never be known completely. It is futile to expect the model to provide design data, such as expected displacements, when there is massive uncertainty in the input data. However, a numerical model is still useful in providing a picture of the *mechanisms* that may occur in particular physical systems. The model acts to educate the intuition of the design engineer by providing a series of cause-and-effect examples. The models may be simple, with assumed data that is consistent with known field data and engineering judgement. It is a waste of effort to construct a very large and complicated model that may be just as difficult to understand as the real case.

Of course, if extensive field data is available, then this may be incorporated into a comprehensive model that can yield design information directly. More commonly, however, the data-limited model does not produce such information directly, but provides insight into mechanisms that may occur. The designer can then do simple calculations based on these mechanisms that estimate the parameters of interest or the stability conditions.

3.10.2 Modeling of Chaotic Systems

In some calculations, especially in those involving discontinuous materials, the results can be extremely sensitive to very small changes in initial conditions, or trivial changes in loading sequence. At first sight, this situation may seem unsatisfactory and may be taken as a reason to mistrust the computer simulations. However, the sensitivity exists in the physical system being modeled. There appear to be a least two sources for the seemingly erratic behavior:

1. There are certain geometric patterns of discontinuities that force the system to choose, apparently at random, between two alternative outcomes; the subsequent evolution depends on which choice is made. For example, Figure 3.46 illustrates a small portion of a jointed rock mass. If block A is forced to move down relative to B, it can either go to the left or to the right of B; the choice will depend on microscopic irregularities in geometry, properties or kinetic energy.

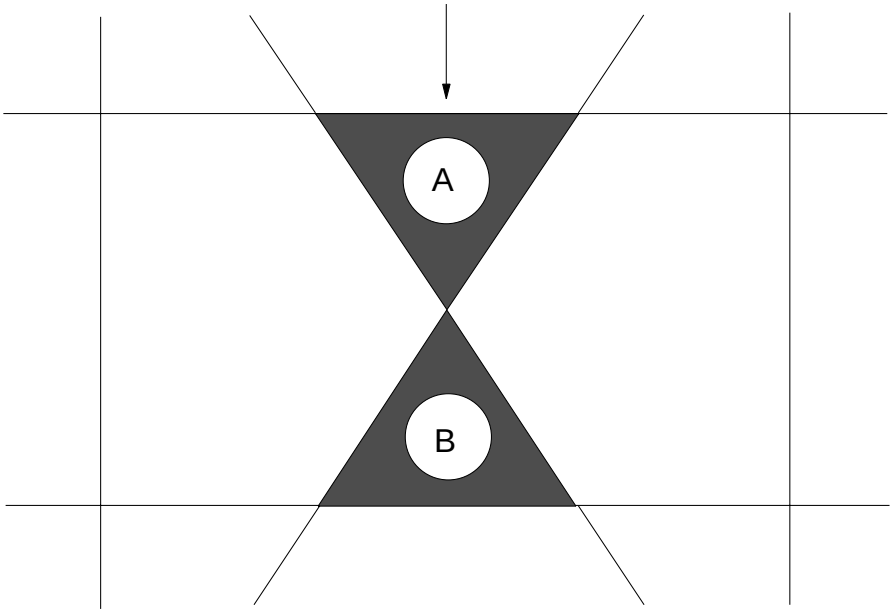

Figure 3.46 A small portion of a jointed rock mass

2. There are processes in the system that can be described as "softening" or, more generally, as cases of positive feedback. In a fairly uniform stress field, small perturbations are magnified in the subsequent evolution because a region that has more strain, softens more and thereby attracts more strain, and so on, in a cycle of positive feedback.

Both phenomena give rise to behavior that is chaotic in its extreme form (Gleick (1987) and Thompson and Stewart (1986)). The study of chaotic systems reveals that the detailed evolution of such a system is not predictable, *even in principle*. The observed sensitivity of the computer model to small changes in initial conditions or numerical factors is simply a reflection of a similar sensitivity in the real world to small irregularities. There is no point in pursuing increasingly more "accurate" calculations, because the resulting model is unrepresentative of the real world, where conditions are not perfect. What should our modeling strategy be in the face of a chaotic system? It appears that the best we can expect from such a model is a finite *spectrum* of expected behavior; the *statistics* of a chaotic system are well-defined. We need to construct models that contain distributions of initial irregularities — e.g., by using *FLAC3D*'s **gauss_dev** or **uniform_dev** parameter on the **PROPERTY** command, or by specifying given distributions with a special *FISH* function. Each model should be run several times, with different distributions of irregularities. Under these conditions, we may expect the fluctuations in behavior to be triggered by the imposed irregularities, rather than by artifacts of the numerical solution scheme. We can express the results in a statistical form.

3.10.3 Localization, Physical Instability and Path-Dependence

In many systems that can be modeled with *FLAC3D*, there may be several paths that the solution may take, depending on rather small changes in initial conditions. This phenomenon is termed *bifurcation*. For example, a shear test on an elastic/plastic material may either deform uniformly, or it may exhibit shear bands, in which the shear strain is localized rather than being uniformly distributed. It appears that if a numerical model has enough degrees-of-freedom (i.e., enough elements), then localization is to be expected. Indeed, theoretical work on the bifurcation process (e.g., Rudnicki and Rice (1975) and Vardoulakis (1980)) shows that shear bands form even if the material does not strain-soften, provided that the dilation angle is lower than the friction angle. The "simple" Mohr-Coulomb material should always exhibit localization if enough elements to resolve one or more localized bands exist. A strain-softening material is more prone to produce bands.

Some computer programs appear incapable of reproducing band formation, although the phenomenon is to be expected physically. However, *FLAC3D* is able to allow bands to develop and evolve, partly because it models the dynamic equations of motion (i.e., the kinetic energy that accompanies band formation is released and dissipated in a physically realistic way). Several papers document the use of two-dimensional *FLAC* in modeling shear band formation (Cundall (1989), (1990) and (1991)). These should be consulted for details concerning the solution process. One aspect that is not treated well by *FLAC3D* is the *thickness* of a shear band. In reality, the thickness of a band is determined by internal features of the material, such as grain size.

These features are not built into *FLAC3D*'s constitutive models. Hence, the bands in *FLAC3D* collapse down to the smallest width that can be resolved by the grid, which is one grid-width if the band is parallel to the grid, or about three grid-widths if the band cuts across the grid at an arbitrary angle. Although the overall physics of band formation is modeled correctly by *FLAC3D*, band thickness and band spacing are grid-dependent. Furthermore, if the strain-softening model is used with a weakening material, the load/displacement relation generated by *FLAC3D* for a simulated test is strongly grid-dependent. This is because the strain concentrated in a band depends on the width of the band (in length units), which depends on zone size, as we have seen. Hence, smaller zones lead to more softening, since we move out more rapidly on the strain axis of the given softening curve. To correct this grid dependence, some sort of length scale must be built into the constitutive model. There is controversy, at present, concerning the best way to do this. It is anticipated that future versions of *FLAC3D* will include a length scale in the constitutive models — probably involving the use of a Cosserat material, in which internal spins and moments are taken into account. In the meantime, the processes of softening and localization may be modeled, but it must be recognized that the grid size and angle affect the results: models must be calibrated for each grid used.

One topic that involves chaos, physical instability and bifurcation is *path-dependence*. In most nonlinear, inelastic systems, there are an *infinite* number of solutions that satisfy equilibrium, compatibility, and the constitutive relations. There is no "correct" solution to the physical problem unless the path is specified. If the path is not specified, all possible solutions are correct. This situation can cause endless debate among modelers and users, particularly if a seemingly irrelevant parameter in the solution process (e.g., damping) is seen to affect the final result. All of the solutions are valid numerically. For example, a simulation of a mining excavation with low damping may show a large overshoot and, hence, large final displacements, while high damping will eliminate the overshoot and give lower final displacements. Which one is more realistic? It depends on the path.

If the excavation is done by explosion (i.e., suddenly), then the solution with overshoot may be the appropriate one. If the excavation is done by pick and shovel (i.e., gradually), then the second case may be more appropriate. For cases in which path-dependence is a factor, modeling should be done in a way that mimics the way the system evolves physically.

4 *FISH* BEGINNER'S GUIDE

4.1 Introduction

FISH is a programming language embedded within *FLAC3D* that enables the user to define new variables and functions. These functions may be used to extend *FLAC3D*'s usefulness or add user-defined features. For example, new variables may be plotted or printed, special grid generators may be implemented, servo-control may be applied to a numerical test, unusual distributions of properties may be specified and parameter studies may be automated.

FISH was developed in response to requests from users who wanted to do things with Itasca software that were either difficult or impossible with existing program structures. Rather than incorporate many new and specialized features into the standard code, an embedded language was provided so that users could write their own functions. Some useful *FISH* functions have already been written; a library of these is provided with the *FLAC3D* program (see Section 3 in the ***FISH* volume**). It is possible for someone without experience in programming to write simple *FISH* functions or to modify some of the simpler existing functions. Section 4.2 contains an introductory tutorial for non-programmers. However, *FISH* programs can also become very complicated (which is true of code in any programming language) — for more details, refer to Section 2 in the ***FISH* volume**.

As with all programming tasks, *FISH* functions should be constructed in an incremental fashion, checking operations at each level before moving on to more complicated code. *FISH* does less error-checking than most compilers, so all functions should be tested on simple data sets before using them for real applications.

FISH programs are simply embedded in a normal *FLAC3D* data file — lines following the word **DEFINE** are processed as a *FISH* function; the function terminates when the word **END** is encountered. Functions may invoke other functions, which may invoke others, and so on. The order in which functions are defined does not matter, so long as they are all defined before they are used (e.g., invoked by a *FLAC3D* command). Since the compiled form of a *FISH* function is stored in *FLAC3D*'s memory space, the **SAVE** command saves the function and the current values of associated variables.

All of the *FISH* language rules and intrinsic functions are discussed in Section 2 in the ***FISH* volume**. This includes rules for syntax, data types, arithmetic, variables and functions. All *FISH* language names are described in Section 2 in the ***FISH* volume**.

4.2 Tutorial

This section is intended for people who have run *FLAC3D* (at least for simple problems) but have not used the *FISH* language — no programming experience is assumed. To get the maximum benefit from the examples given here, you should try them out with *FLAC3D* running interactively. The short programs may be typed in directly. After running an example, give the *FLAC3D* command **NEW**, to "wipe the slate clean," ready for the next example. Alternatively, the more lengthy programs may be created on file and **CALL**ed when required.

Type the lines in Example 4.1 after *FLAC3D*'s command prompt, pressing <ENTER> at the end of each line.

Example 4.1 Defining a FISH function

```
def abc
  abc = 22 * 3 + 5
end
```

Note that the command prompt changes to **Def>** after the first line has been typed in. Then it changes back to the usual prompt when the **END** command is entered. This change in prompt lets you know whether you are sending lines to *FLAC3D* or to *FISH*. Normally, all lines following the **DEFINE** statement are taken as part of the definition of a *FISH* function (until the **END** statement is entered). However, if you type in a line that contains an error (e.g., you type the **=** sign instead of the **+** sign), then you will get the *FLAC3D* prompt back again. In this case, you should give the **NEW** command and try again from the beginning. Since it is very easy to make mistakes, *FISH* programs are normally typed into a file using an editor. These are then **CALL**ed into *FLAC3D* just like a regular *FLAC3D* data file. We will describe this process later; for now, we'll continue to work interactively. Assuming that you typed in the preceding lines without error, and that you now see the *FLAC3D* prompt `Flac3D>`, you can "execute" the function **abc*** defined earlier in Example 4.1 by typing the line

```
print abc
```

The message

```
abc =  71
```

should appear on the screen. By defining the symbol **abc** (using the **DEFINE – END** construction, as in Example 4.1), we can now refer to it in many ways using *FLAC3D* commands.

For example, the **PRINT** command causes the value of a *FISH* symbol to be displayed; the value is computed by the series of arithmetic operations in the line

```
abc = 22 * 3 + 5
```

---

* We will use **courier boldface** to identify user-defined *FISH* functions and declared variables in the text.

This is an "assignment statement." If an equal sign is present, the expression on the right-hand side of the equal sign is evaluated and given to the variable on the left-hand side. Note that arithmetic operations follow the usual conventions; addition, subtraction, multiplication and division are done with the signs **+**, **-**, ***** and **/**, respectively. The sign ^ denotes "raised to the power of."

We now type in a slightly different program (using the **NEW** command to erase the old one):

Example 4.2 Using a variable

```
new
def abc
  hh = 22
  abc = hh * 3 + 5
end
```

Here we introduce a "variable," **hh**, which is given the value of 22 and then used in the next line. If we give the command **PRINT abc**, then exactly the same output as in the previous case appears. However, we now have two *FISH* symbols; they both have values, but one (**abc**) is known as a "function," and the other (**hh**) as a "variable." The distinction is as follows.

> *When a FISH symbol name is mentioned (e.g., in a* **PRINT** *statement), the associated function is executed if the symbol corresponds to a function. However, if the symbol is not a function name, then the current value of the symbol is used.*

The following experiment may help to clarify the distinction between variables and functions. (Before doing the experiment, note that *FLAC*^{3D}'s **SET** command can be used to set the value of any user-defined *FISH* symbol, independent of the *FISH* program in which the symbol was introduced.) Now type in the following lines without giving the **NEW** command, since we want to keep our previously entered program in memory.

Example 4.3* SET*ting variables

```
set abc=0 hh=0
print hh
print abc
print hh
```

The **SET** command sets the values of both **abc** and **hh** to zero. Since **hh** is a variable, the first **PRINT** command simply displays the current value of **hh**, which is zero. The second **PRINT** command causes **abc** to be executed (since **abc** is the name of a function); the values of both **hh** and **abc** are thereby recalculated. Accordingly, the third **PRINT** statement shows that **hh** has indeed been reset to its original value. As a test of your understanding, you should type in the slightly modified sequence shown in Example 4.4, and figure out why the displayed answers are different.

Example 4.4 Test your understanding of function and variable names

```
new
def abc
  abc = hh * 3 + 5
end
set hh=22
print abc
set abc=0 hh=0
print hh
print abc
print hh
```

At this stage, it may be useful to list the most important *FLAC3D* commands that directly refer to simple *FISH* variables or functions. (In Table 4.1, ***var*** stands for the name of the variable or function.)

Table 4.1 Commands that directly refer to FISH names

PRINT	***var***
SET	***var*** = ***value***
HISTORY	***var***

We have already seen examples of the first two (refer to Examples 4.3 and 4.4); the third case is useful when histories of things that are not provided in the standard *FLAC3D* list of history variables are required. Example 4.5 shows how the total load on the top platen of a triaxial test sample can be stored as a history.

Example 4.5 Capturing the history of a FISH variable

```
new
gen zone brick size 1 2 1
model mohr
prop shear=1e8 bulk=2e8 &
     cohes=1e5 tens=1e10
fix x y z        range y -0.1 0.1
apply yvel -1e-5 range y  1.9 2.1
def get_ad
   ad1 = gp_near(0,2,0)
   ad2 = gp_near(1,2,0)
   ad3 = gp_near(0,2,1)
   ad4 = gp_near(1,2,1)
end
```

```
get_ad
def load
   load=gp_yfunbal(ad1)+gp_yfunbal(ad2)+gp_yfunbal(ad3)+gp_yfunbal(ad4)
end
hist load
hist gp ydis 0,6,0
step 1000
plot his 1 vs -2
```

Note that the *FISH* variable **load** is equal to the sum of four other variables, **gp_yfunbal*(index)***. The *FISH* grid variable **gp_yfunbal()** is an example of a grid quantity that is available within a *FISH* program; there is a complete list of these in Section 2.5.3 in the ***FISH* volume**. Grid variables are simply pre-defined named quantities that relate to the *FLAC3D* grid.

In Example 4.5, **gp_yfunbal()** is the y-component of the unbalanced gridpoint force; each instance of **gp_yfunbal()** must be followed by a gridpoint memory address (or pointer). The address is found with the function **get_ad**, which uses the *FISH* gridpoint variable **gp_near** to find the address of the gridpoint closest to the (x,y,z) global coordinates (0,2,0), (1,2,0), (0,2,1) and (1,2,1). The derived variable **load**, which is the sum of the four top forces, is calculated whenever history points are taken (every ten steps, by default). At the end of the run, we simply plot out the history of **load** (history 1) just like any other history. Similarly, we may use *FISH* functions to plot out a history of any quantity we wish, no matter how complicated the formula to describe it might be.

In addition to the above-mentioned pre-defined variable names, there are many other pre-defined objects available to a *FISH* program. These fall into several classes; one such class consists of *scalar* variables, which are single numbers — for example,

clock	clock time in hundredths of a second
unbal	maximum unbalanced force
xgrav	x-component of gravity
pi	π
step	current step number
urand	random number drawn from uniform distribution between 0.0 and 1.0

This is just a small selection — the full list is given in Section 2.5.2 in the ***FISH* volume**.

Another useful class of built-in objects is the set of *intrinsic functions*, which enables things like sines and cosines to be calculated from within a *FISH* program. A complete list is provided in Section 2.5.4 in the ***FISH* volume**; a few are given below.

abs(*a*)	absolute value of ***a***
cos(*a*)	cosine of ***a*** (***a*** is in radians)

log(*a*)	base-ten logarithm of ***a***
max(*a*,*b*)	returns maximum of ***a***, ***b***
sqrt(*a*)	square root of ***a***

An example in the use of intrinsic functions will be presented later, but now we must discuss one more way in which a *FLAC3D* data file can make use of user-defined *FISH* names.

> *Wherever a number is expected in a FLAC3D input line, you may substitute the name of a FISH variable or function.*

This simple statement is the key to a very powerful feature of *FISH* that allows such things as ranges, applied stresses, properties, etc., to be computed in a *FISH* function and used by *FLAC3D* input in symbolic form. Hence, parameter changes can be made very easily, without the need to change many numbers in an input file.

As an example, let us assume that we know the Young's modulus and Poisson's ratio of a material. Since *FLAC3D* needs the bulk and shear moduli, we may derive these with a *FISH* function, using Eqs. (4.1) and (4.2):

$$G = \frac{E}{2(1+\nu)} \tag{4.1}$$

$$K = \frac{E}{3(1-2\nu)} \tag{4.2}$$

Coding Eqs. (4.1) and (4.2) into a *FISH* function (called **derive**) can then be done as shown in Example 4.6:

Example 4.6 FISH functions to calculate bulk and shear moduli

```
new
def derive
  s_mod = y_mod / (2.0 * (1.0 + p_ratio))
  b_mod = y_mod / (3.0 * (1.0 - 2.0 * p_ratio))
end
set y_mod = 5e8 p_ratio = 0.25
derive
print b_mod s_mod
```

Note that here we execute the function **derive** by giving its name by itself on a line; we are not interested in its *value*, only what it *does*. If you run this example, you will see that values are

computed for the bulk and shear moduli, **b_mod** and **s_mod**, respectively. These can then be used, in symbolic form, in *FLAC3D* input as shown in Example 4.7.*

Example 4.7 Using symbolic variables in FLAC3D input

```
gen zone brick size 2,2,2
model elastic
prop bulk=b_mod shear=s_mod
print zone prop bulk
print zone prop shear
```

The validity of this operation may be checked by printing out **bulk** and **shear** in the usual way. In these examples, our property input is given via the **SET** command — i.e., to variables **y_mod** and **p_ratio**, which stand for Young's modulus and Poisson's ratio, respectively.

Note that there is great flexibility in choosing names for *FISH* variables and functions; the underline character (_) may be included in a name. Names must begin with a non-number and must not contain any of the arithmetic operators (+, –, /, * or ^). See Section 2.2.2 in the ***FISH*** **volume** for a list of symbols to avoid. A chosen name should not be the same as one of the built-in (or reserved) names; Table 2.1 in Section 2.2.2 in the ***FISH*** **volume** contains a complete list of names to be avoided, as well as some rules that should be followed. Also note that parentheses were used in the preceding example. These should be used whenever it is necessary to make clear the order in which arithmetic operations are to be done.

In the preceding examples, we checked the computed values of *FISH* variables by giving their names explicitly as arguments to a **PRINT** command. Alternatively, we can list all current variables and functions. A printout of all current values, sorted alphabetically by name, is produced by giving the command

```
print fish
```

We now examine ways in which decisions can be made, and repeated operations done, in *FISH* programs. The following *FISH* statements allow specified sections of a program to be repeated many times.

LOOP ***var (expr1, expr2)***

ENDLOOP

---

* In **safe** mode, the *FISH* variable must be preceded by an @ symbol — see Section 2.2.2 in the ***FISH*** **volume** and the **SET** command in Section 1.3 in the **Command Reference**.

The words **LOOP** and **ENDLOOP** are *FISH* statements, the symbol ***var*** stands for the loop variable, and ***expr1*** and ***expr2*** stand for expressions (or single variables). Example 4.8 shows the use of a loop (or repeated sequence) to produce the sum and product of the first ten integers.

Example 4.8 Controlled loop in FISH

```
new
def xxx
  sum  = 0
  prod = 1
  loop n (1,10)
    sum  = sum + n
    prod = prod * n
  end_loop
end
xxx
print sum, prod
```

In this case, the loop variable **n** is given successive values from 1 to 10, and the statements inside the loop (between the **LOOP** and **ENDLOOP** statements) are executed for each value. As mentioned, variable names or an arithmetic expression could be substituted for the numbers 1 or 10.

A practical use of the **LOOP** construct is to install a nonlinear initial distribution of elastic moduli in a *FLAC3D* grid. Suppose that the Young's modulus at a site is given by Eq. (4.3):

$$E = E_\circ + c\sqrt{z} \tag{4.3}$$

where z is the depth below surface, and c and $E_\circ$ are constants. We write a *FISH* function to install appropriate values of bulk and shear modulus in the grid, as in Example 4.9.

Example 4.9 Applying a nonlinear initial distribution of moduli

```
new
gen zone brick p0 (0,0,0) p1 (-10,0,0) p2 (0,10,0) p3 (0,0,-10)
model elas
def install
    pnt = zone_head
    loop while pnt # null
        z_depth = -z_zcen(pnt)
        y_mod = y_zero + cc * sqrt(z_depth)
        z_prop(pnt, 'shear') = y_mod / (2.0*(1.0+P_ratio))
        z_prop(pnt, 'bulk')  = y_mod / (3.0*(1.0-2.0*P_ratio))
        pnt = z_next(pnt)
    end_loop
```

```
end
set p_ratio=0.25 y_zero=1e7 cc=1e8
install
plot block prop bulk
```

Again, you can verify correct operation of the function by printing or plotting shear and bulk moduli.

In the function **install**, the loop scans all zones beginning with **zone_head**, which is the address of the first zone in the zone list. The *FISH* statement **LOOP WHILE** is a variation of **LOOP** that executes the loop until the test condition is met — i.e., until the address **pnt** equals zero (**pnt # null** means **pnt** not equal to zero). This condition identifies the last zone in the zone list. Inside the loop, the z-coordinate of each zone centroid is used to calculate the Young's modulus, given in Eq. (4.3). We assume that the datum (or ground surface reference point) is at $z = 0$. Grid values for bulk and shear moduli are calculated as in Example 4.6. The variables **z_zcen(pnt)**, **z_prop(pnt, 'shear')** and **z_prop(pnt, 'bulk')** are *zone* variables. (Recall that we talked about the *gridpoint* variable **gp_yfunbal(pnt)** earlier.) Here, we set properties directly from within a *FISH* function, rather than with a **PROP** command as in our earlier example.

Having seen several examples of *FISH* programs, let's briefly examine the question of program syntax and style. A complete *FISH* statement must occupy one line; there are no continuation lines. If a formula is too long to fit on one line, then a temporary variable must be used to split the formula. Example 4.10 shows how this can be done.

Example 4.10 Splitting lines

```
new
def long_sum  ;example of a sum of many things
  temp = v1 + v2 + v3 + v4 + v5 + v6 + v7 + v8 + v9 + v10
  long_sum = temp + v11 + v12 + v13 + v14 + v15
end
```

In this case, the sum of fifteen variables is split into two parts. Also note the use of the semicolon in line 1 of Example 4.10 to indicate a comment. Any characters that follow a semicolon are ignored by the *FISH* compiler, but they *are* echoed to the log file. It is good programming practice to annotate programs with informative comments. Some of the programs have been shown with *indentation* — that is, space inserted at the beginning of some lines to denote a related group of statements. Any number of space characters may be inserted (optionally) between variable names and arithmetic operations to make the program more readable. Again, it is good programming practice to include indentation to indicate things like loops, conditional clauses and so on. Spaces in *FISH* are "significant" in the sense that space characters may not be inserted into a variable or function name.

One other topic that should be addressed now is that of variable *type*. You may have noticed, when printing out variables from the various program examples, that numbers are either printed without decimal points or in "E-format" — that is, as a number with an exponent denoted by "E." At any

instant in time, a *FISH* variable or function name is classified as one of four types: *integer*, *floating-point*, *string* or *pointer*. These types may change dynamically, depending on context, but the casual user should not normally have to worry about the type of a variable, since it is set automatically. Consider Example 4.11.

Example 4.11 Variable types

```
new
def haveone
  aa = 2
  bb = 3.4
  cc = 'Have a nice day'
  dd = aa * bb
  ee = cc + ', old chap'
end
haveone
print fish
```

The resulting screen display looks like this:

```
                Value    Name
                -----    ----
                    2    aa
           3.4000e+000    bb
            - string -    cc
           6.8000e+000    dd
            - string -    ee
                    0    haveone
```

The variables **aa**, **bb** and **cc** are converted to *integer*, *float* and *string*, respectively, corresponding to the numbers (or strings) that were assigned to them. Integers are exact numbers (without decimal points) but are of limited range; floating-point numbers have limited precision (about 15 decimal places), but are of much greater range; string variables are arbitrary sequences of characters; *pointers* are used to address internal variables in *FLAC3D*. There are various rules for conversion between the four types. For example, **dd** becomes a floating-point number, because it is set to the product of a floating-point number and an integer; the variable **ee** becomes a string because it is the sum (concatenation) of two strings. The topic can get quite complicated, but it is fully explained in Sections 2.2.4 and 2.2.5.

There is another language element in *FISH* that is commonly used — the **IF** statement. The following three statements allow decisions to be made within a *FISH* program.

IF *expr1 test expr2* **THEN**

ELSE

ENDIF

These statements allow conditional execution of *FISH* program segments; **ELSE** and **THEN** are optional. The item ***test*** consists of one of the following symbols or symbol pairs.

= # > < >= <=

The meanings are standard except for #, which means "not equal." The items ***expr1*** and ***expr2*** are any valid expressions or single variables. If the test is true, then the statements immediately following **IF** are executed until **ELSE** or **ENDIF** is encountered. If the test is false, the statements between **ELSE** and **ENDIF** are executed if the **ELSE** statement exists; otherwise, the program jumps to the first line after **ENDIF**. The action of these statements is illustrated in Example 4.12.

Example 4.12 Action of the* IF ELSE ENDIF *construct

```
new
def abc
  if xx > 0 then
    abc = 33
  else
    abc = 11
  end_if
end
set xx = 1
print abc
set xx = -1
print abc
```

The displayed value of **abc** in Example 4.12 depends on the set value of **xx**. You should experiment with different test symbols (e.g., replace > with <).

Until now, our *FISH* programs have been invoked from *FLAC3D*, either by using the **PRINT** command, or by giving the name of the function on a separate line of *FLAC3D* input. It is also possible to do the reverse — that is, to give *FLAC3D* commands from within a *FISH* function. Most valid *FLAC3D* commands can be embedded between the following *FISH* statements.

COMMAND
ENDCOMMAND

There are two main reasons for sending out *FLAC3D* commands from a *FISH* program. First, it is possible to use a *FISH* function to perform operations that are not possible using the pre-defined variables that we already discussed. Second, we can control a complete *FLAC3D* run with *FISH*. As an illustration of the first use of the **COMMAND** statement, we can write a *FISH* program to install a number of cable elements at different depths in a material. When many cable elements are required, it becomes tedious to type many separate **SEL cable** commands, each with different grid values. However, with *FISH*, we can send out the commands from within a loop and assign the location of the cable ends automatically each time around the loop, as illustrated in Example 4.13.

Example 4.13 Automated placing of cable elements

```
new
gen zone brick size 10 3 5
def place_cables
    loop n (1,5)
        z_d = float(n) - 0.5
        command
            sel cable beg 0.0,1.5,z_d end 7.0,1.5,z_d nseg 7
        end_command
     end_loop
end
place_cables
plot grid sel geom red
```

After entering these statements, you should do a printout and plot of the cable data to verify that five cables have been created, and that they are located at the appropriate positions in the grid. In the example, we use variable **z_d** as a parameter in the function **place_cables**; **z_d** is the z-coordinate of the endpoints of each cable.

We can modify this example to perform a construction sequence of excavation and installation of cables. This illustrates the second use of **COMMAND**. We use the **FREE** and **SOLVE** commands to "excavate" the boundary plane at $x = 0$ in five steps. At the end of each step, we install a row of three cables and then excavate the next section of the boundary.

Example 4.14 Sequence of excavation and cable placement

```
new
gen zone brick size 10 3 5

end

place_cables

save cab_end.sav
plot sketch sel cable force red
```

We have now covered some of the aspects of the *FISH* language and how it interacts with *FLAC*^{3D}. A complete guide to the language is contained in Section 2 in the ***FISH* volume**, detailed information on *FISH* language names is given in Section 2 in the ***FISH* volume**, and some examples are provided in Section 3 in the ***FISH* volume**.

5 MISCELLANEOUS

5.1 *FLAC3D* Runtime Benchmark

FLAC3D has been tested on a number of different computers. The calculation rates are compared here for a 125-zone model of elastic material subject to uniaxial loading. The model is run for 50,000 steps, and the rate is calculated by a *FISH* function. The data file is given in Example 5.1, and Table 5.1 summarizes the calculation rates for different computers.

Example 5.1 Benchmark data file — "TIMING.DAT"

```
def rate
   rate = (t1 - t0) / 6250.0
end
def time0
   t0 = clock / 100.0
end
def time1
   t1 = clock / 100.0
end
gen zone brick size 5,5,5
model elas
prop bulk 1e8 shear 1e7
fix y range y -0.1 0.1
apply syy -1.0e6 range y 4.9,5.1
time0
step 50000
time1
print rate
return
```

Table 5.1 FLAC^{3D} runtime calculation rates

5.2 Error Reporting

Although *FLAC3D* has been tested extensively, it is almost impossible to test all available combinations of options in a code as complex as *FLAC3D*. For this reason, some errors may have evaded our notice. If you discover a genuine bug, please let us know as soon as possible so that we may correct it.

5.2.1 Reporting via the Internet

Itasca's current Internet e-mail address is

software@itascacg.com

Please include the same information requested on the error notification form (in Section 5.2.2), followed by the contents of your data file.

5.2.2 Reporting via Fax

A sample form for you to copy and mail or fax to us is given on the next page. Please fill out the form completely, as this is the minimum information we will need to find and correct the error. The sample file should, if possible, contain the minimum number of commands necessary to produce the error. We may have to contact you for further information if we are unable to duplicate the error. Be aware that it is always possible that the error is peculiar to your hardware, making it impossible for us to duplicate.

5.3 Technical Support Service

Itasca and its offices and agents will provide telephone support, at no cost, to assist code owners with the installation of Itasca codes on their computer systems. Additionally, general assistance may be provided to aid the owner in understanding the capabilities of the various features of the code. However, no-cost assistance is *not* provided for help in applying an Itasca code to specific user-defined problems.

Questions should, in the first instance, be directed to the office or agent where *FLAC3D* was purchased.

INTER-OFFICE CORRESPONDENCE

DATE: September 4, 2012

FROM: R. F. Kehrman LOCATION: Regulatory Compliance

TO: R. R. Chavez LOCATION: Regulatory Compliance

SUBJECT: REVISED CALCULATIONS TO SUPPORT PANEL CLOSURE

Attached is a paper detailing the information needed to evaluate Panel Closure performance. The paper establishes that the compliance point for Panel Closure is the WIPP Site Boundary and assumes an individual resides at the point of greatest concentration. The risk level to this receptor is one excess cancer death in one million or 10^{-6}. This is consistent with the design criteria in the WIPP Permit (Permit Attachment G1, Section 1.3.2.)

The paper assumes that the repository is filled to capacity. That is, risk is calculated when all panels are filled and closed except for Panel 10, which is filled, but not yet closed. This approach is consistent with the original Panel Closure Design submitted in the original Permit Application.

One major difference from the original application is the recalculation of the VOC source term. While the original modeling relied on samples from 930 drums to TRU mixed waste, the current calculation uses over 130,000 headspace measurements made under the Permit, primarily before October 2006. The calculation of the revised source term is included with the Attachment.

Another difference is that I revised the number of containers per room and the filter diffusion rates to reflect the composite of the disposed waste in Panels 1 through 5.

My calculations are documented in the attached paper. I have updated these calculations to accommodate the most recent EPA recommended risk factors and to correct the exposure frequency and duration for non-waste workers on the surface. Previously, these exposure factors were treated as the same as those for members of the public. I also changed the number of containers in the previous version of the paper from 4,800 to 6,050 per room to reflect the number of filters emitting VOCs. This was necessary since many containers have more than one filter.

For convenience, I have also attached my spreadsheet. The last page of the spreadsheet evaluates the effects of leakage through closed panels. Panels can tolerate a leakage equivalent to about 2,000 times the gas generation rate of 0.5 moles/drum/year. There is a leakage rate that will make compliance difficult. This appears to be on the order of 50 cubic feet per minute.

The attached information may be useful to the Panel Closure design team in that it provides the methodology for determining risk consistent with the RCRA regulations and our original Permit Application.

If you have any questions, please call me at 234-7210.

ESTABLISHING VOLATILE ORGANIC COMPOUND LIMITS FOR THE PANEL CLOSURE DESIGN

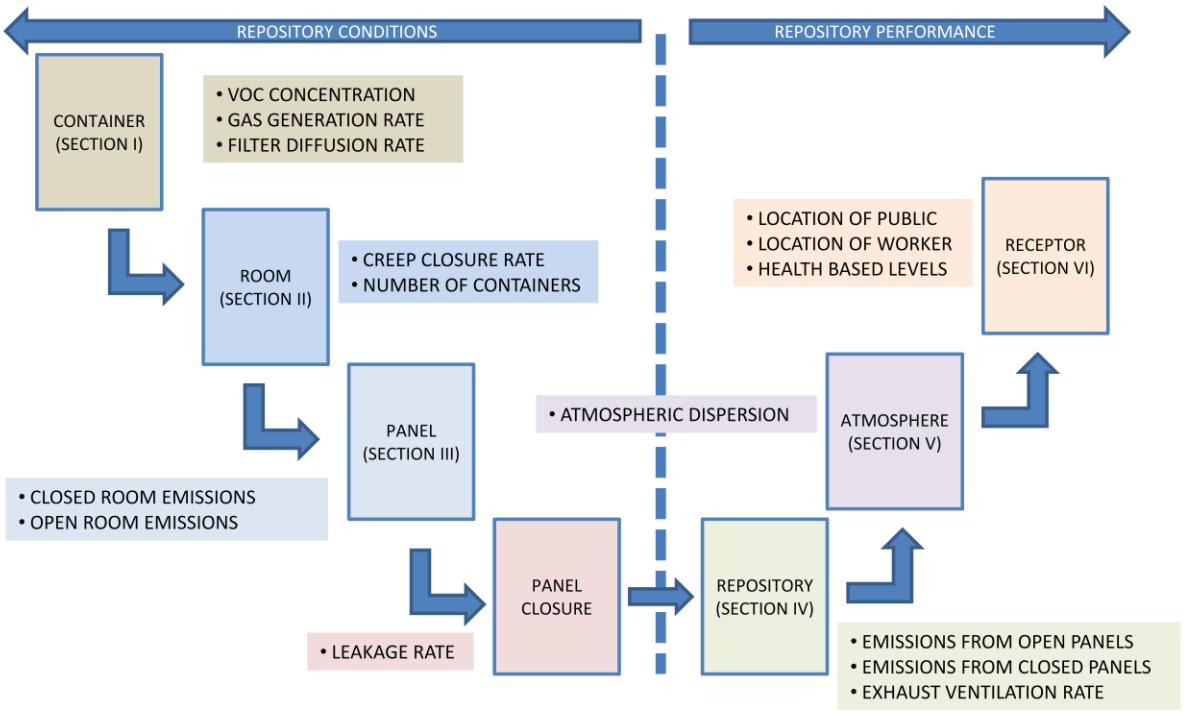
R. F. Kehrman

Figure 1 is a block diagram of the elements that go into preparing a risk model to demonstrate operational impacts due to emissions from the Waste Isolation Pilot Plant repository. The goal of this discussion is to provide information needed to specify the design of the Panel Closure which will serve to assure the performance standards to the right on the diagram are met for the conditions in the repository shown on the left in Figure 1. When the original Part B Permit Application for the Waste Isolation Pilot Plant (WIPP) (U. S. Department of Energy, 1996 a) facility was submitted in 1996, one of the design parameters for Panel Closure was that "the panel closure system shall limit the migration of [volatile organic compounds] VOCs to the compliance point so that compliance is achieved by at least one order of magnitude." This criterion has been changed for the current design to only require compliance without an additional compliance margin. The following discusses each element in the order indicated by the Roman Numerals on the Figure.

FIGURE 1: Elements of the Waste Isolation Pilot Plant Air Exposure Pathway



I. Container

VOC CONCENTRATION Information needed on the container scale for air dispersion modeling is the average concentration of VOCs in the headspace of the container which defines the release source term and the gas generation rate which is a driving force to move VOCs from closed rooms and panels into the repository ventilation system. The VOC source term used for the original Panel Closure design effort was developed based on a limited sampling program conducted in Idaho and at Rocky Flats. Subsequent

to that time, a weighted average source term was developed using the same data, however, a weighting process was developed to accommodate the wide variety of waste forms and to weight them in accordance with their prevalence. The process for developing the weighted average source term is described in Appendix C2 of the 1996 Permit Application (U. S. Department of Energy, 1996 a). The results are summarized in Table 1. In 2010, the source term was revised using the same methodology; however, over 130,000 headspace gas measurements were available (Kehrman, 2011). The revised source term is shown in Table 1. The values in Table 1 represent the average concentration that would be expected in a filled, closed room.

TABLE 1: TRU Waste VOC Source Term

Constituent	Original Weighted Average (ppmv)	Revised Weighted Average (ppmv)
ACETONE	79.8	53.1

O-XYLENE	16.0	3.8

GAS GENERATION Appendix D11 of the 1996 Permit Application (U. S. Department of Energy, 1996 a) includes information on gas generation by WIPP waste. Of the gas-generating mechanisms described in Appendix D11, microbial degradation will contribute the most to the generation rate during the time periods of interest. The best estimate for gas generation from microbial degradation under humid conditions is 0.1 moles of gas per drum per year.

Although Appendix D11 states that the maximum expected value for any one drum of waste is 0.4 moles per drum per year, the lowest expected value for any one drum is 0 moles per drum per year. A discussion of the relationship between gas generation, brine inflow, and creep closure can be found in Section I-1e(4). In reality, under the conditions that will initially exist in a closed panel, the predominant degradation mechanisms may consume gas at a rate faster than it is produced. This outcome is a function of the availability of nutrients to sustain microbial activities. Indications of gas consumption activities are in Francis and Gillow (Francis, A.J. and J.B. Gillow, 1994), where they reported 200-day experiments (see Appendix D11). These data are summarized in Table 2.

TABLE 2: TRU Waste Container Gas Generation Rates Due to Microbial Degradation

	High	Low	Expected
Gas-Generation Rate moles/drum/year	0.4	0.0	0.1

FILTER DIFFUSION RATE The rate at which VOCs will be emitted from containers is a function of the diffusion rate for the individual filter on the containers. These filters are placed on every container to prevent the buildup of hydrogen as the result of radiolysis. Diffusion is relevant for open rooms only. Closed rooms are assumed to be in equilibrium with the average VOC concentration in the containers. Container filters are specified with a hydrogen diffusion rate. The methodology for calculating the VOC diffusion rate based on the hydrogen rate is given in Chapter 5 of the 1996 No-Migration Variance Petition (U. S. Department of Energy, 1996 b).

At the time the original documents were prepared, the number of filters being used was limited to two. Now there are a large number of filters in use. Since filter diffusivity is a parameter that is tracked in the WIPP Waste Data System, filter diffusion rates were compiled as shown in Table 3. These data yield an average filter H_2 diffusion rate for the repository of 1.25×10^{-5} mole/s/mole fraction/drum.

II. Room

CREEP CLOSURE RATE The average creep closure rate will result in a reduction of the panel void volume of 812 m^3 per year for each panel. Calculations in Appendix D9 of the 1996 Permit Application (U. S. Department of Energy, 1996 a) convert this rate at which air is "squeezed" out of the room to an equivalent gas generation rate of 0.4 moles/drum/year. This is depicted in Table 4.

TABLE 4: Effective Gas Generation Rate

Gas-Generation Rate	moles/drum/year
Microbial Degradation	0.1
Creep Closure	0.4
Total Effective Gas Generation Rate	0.5

NUMBER OF CONTAINERS The original assumption was that each Panel would contain 81,000 containers. This number is important because emissions are related to the filter diffusivity associated with each container; therefore the number of filters emitting VOCs to a room that is being filled is part of the calculation of releases. Closed rooms are unventilated and are conservatively assumed to be at the average concentration of the containers that were disposed and emissions are only related to the gas generation rate and creep closure rate (i.e., equivalent gas generation rate). Table 5 is a compilation of the actual distribution of containers in the five filled panels and Room 7 of Panel 6. These data indicate that a reasonable average for the number of containers per room is about 4,770. Using the ratio of total filters to total containers in Table 3, this number of containers contains about 6,050 filters per room.

TABLE 5: Number of Containers Disposed in Each Panel

Container Type	Panel 1	Panel 2	Panel 3	Panel 4	Panel 5	Panel 6	Container Total
55-gallon drum	38,139	23,865	8,394	12,858	21,255	3,798	108,309
Standard waste box	1,239	3,176	1,730	1,405	2,200	594	10,344
Ten drum overpack	35	1,451	2,227	1,048	788	103	5,652
85-gallon drum	2	0	0	3	0	0	5
100-gallon drum	0	1,278	5,409	11,050	9,951	879	28,567
Standard large box 2	0	0	0	0	0	2	2
Panel Total	39,415	29,770	17,760	26,364	34,194	5,376	152,879
Rooms filled in Panel	4.8	6.6	6.7	6.7	6.7	1.0	32.0
Containers per room	8,211	4,580	2,691	3,995	5,181	5,376	4,777

Note: A room is considered to have 567 linear feet of disposal space. Since Room 1 only has 367 feet (i.e., no waste is placed in the intake or exhaust drifts, a full panel in Table 5 is considered to have 6.7 Rooms

III. Panel

Emission rates from filled rooms depend on whether or not the room is open to the ventilation system. Emissions from open rooms depend on the emission rates through filters and the ventilation rate; emissions from closed rooms depend on the gas generation rate and the volumetric reduction in room volume due to creep closure. For Panel Closure modeling, the most conservative condition is when a panel has six filled and closed rooms and one filled room that remains open. Note that it is conservatively assumed that the average drum headspace concentrations serve as a constant source of VOCs.

OPEN ROOM EMISSIONS The open room emission rate is dependent on the number of drums that have been emplaced in the room and the diffusion of VOCs across the drum vent filters. Assuming a continuous fresh air flow across the filters, VOCs will diffuse from the drums at a rate that is dependent on the concentration gradient across the filters and the diffusion properties of the VOCs. The open room emission rate is calculated using the equation

where

$AORE_{VOC}$ = average open room VOC emission rate, mole/room/year
ADE_{VOC} = average drum VOC emission rate, mole/drum/year
nD = number of drums in the room, drum/room.

EMISSIONS FROM CLOSED ROOMS During the placement of waste at WIPP, as individual rooms are filled; ventilation barriers will be used to eliminate ventilation through the filled rooms and to isolate these rooms. Similarly, closure systems will be used to isolate wastes in a full panel and to remove these filled panels from ventilation. Consequently, the open panel emission rate is dependent on the number of full rooms that have ventilation barriers and the number of drums in rooms without ventilation barriers.

As described previously, VOCs will diffuse from the drums at a rate dependent on the concentration gradient across these filters. After a room is filled and the ventilation barrier is installed, the assumption is that fresh air will no longer flow across the waste drums, and VOC concentrations in the dead air

space above the filter will begin to build up and approach the concentrations in the drum headspace. Therefore, the concentration of VOCs that would be present in the filled room atmosphere would be equivalent to the average drum headspace concentration. It is conservatively assumed that the average drum headspace concentrations serve as a constant source of VOCs.

The ventilation barrier consists of low-permeability materials that restrict ventilation flow through a room. Thus, migration of VOCs past the barriers is assumed to only occur by displacement due to room volume reduction that results from creep closure and by pressurization of the room due to continued gas generation from the waste. Based on discussions above (Table 4), the total effective gas generation rate is 0.5 mole/drum/year. (Note that this equates to a flow rate of 0.067 ft^3 per minute.)

Using this effective gas generation rate for a room of containers that has the ventilation barrier in place, the closed room emission rate for each VOC is calculated as:

where

$ACRE_{VOC}$	=	average closed room VOC emission rate, mole/room/year
GR	=	effective gas generation rate, mole/drum/year
N_{drums}	=	number of drums in a room
MF_{VOC}	=	VOC mole fraction, mole/mole

IV. Repository

EMISSIONS FROM OPEN PANELS

The open panel emission rate for each VOC is based on the number of full rooms, the number of drums in the open room, and the emission rates from each type of room. This can be calculated as follows:

where

$AOPE_{VOC}$	=	average open panel VOC emission rate, mole/panel/year
$AORE_{VOC}$	=	average open room VOC emission rate, mole/room/year
$ACRE_{VOC}$	=	average closed room VOC emission rate, mole/room/year
R_o	=	number of open rooms in the open panel, 1 room/panel
R_c	=	number of closed rooms in the open panel, room/panel

EMISSIONS FROM CLOSED PANELS Volatile organic compounds will diffuse from the drums at a rate dependent on the concentration gradient across the filters. As the concentration gradient decreases, the diffusion rate of each VOC decreases. After a panel is closed, fresh air will no longer flow across the waste drums, and VOC concentrations in the air space above the filter will begin to build up and approach the concentrations in the drum headspace. Therefore, the concentration of VOCs that would be present in the panel atmosphere would be equivalent to the average drum headspace concentration.

For a closed panel of N drums, the closed panel emission rate for each VOC is calculated as:

where

$ACPE_{VOC}$ = average closed panel VOC emission rate, mole/panel/year
GR = effective gas generation rate, mole/drum/year
N_{drums} = number of drums in a panel
MF_{VOC} = VOC mole fraction, mole/mole

The emission rate from the repository can then be calculated as the sum of the open panel and closed panel rates:

where

EC_{VOC} = the emission rate for VOC in mole/year
P_O = the number of open panels
P_C = the number of closed panels

V. Atmosphere

ATMOSPHERIC DISPERSION This section presents the results of air dispersion modeling performed inside and outside the WIPP site boundary. The modeling was performed to evaluate four specific scenarios: the Boundary Public, Livingston Ridge Rancher (grazing allotment on the north side of the WIPP site), Antelope Ridge Rancher (grazing allotment on the south side of the WIPP site), and Surface Worker. The Long-Term Version of the Industrial Source Complex (ISCLT3) model, (U.S. Environmental Protection Agency, 1995), was used for the original air dispersion modeling. Concentrations were modeled in accordance with (U.S. Environmental Protection Agency, 1992) EPA (1992). Details of the modeling are described in Appendix D10 of the 1996 Permit Application. The modeling produced the air dispersion factors (ADFs) listed in the center column of Table 6. In 2010 the modeling was updated in order to use newer EPA analytical tools (AERMOD) and updated physical conditions (new buildings, three exhaust stacks) (URS Corporation, 2010). The revised ADFs are in the right column in Table 11.

TABLE 6: Air Dispersion Factors for WIPP Site Areas

Area	Original Air Dispersion Factor (ADF)	Revised Air Dispersion Factor (ADF)
WIPP Site Boundary	1.2×10^{-4}	8.78×10^{-5}
Livingston Ridge Allotment	9.8×10^{-5}	1.76×10^{-4}
Antelope Ridge Allotment	6.7×10^{-5}	6.72×10^{-4}
Training Building	1.23×10^{-2}	1.14×10^{-2}

VI. RECEPTOR

LOCATION OF PUBLIC AND WORKERS Three classes of exposed individuals (receptors) were presented in Appendix D9 of the 1996 Permit Application (U. S. Department of Energy, 1996 a); a surface worker, an underground worker, and a member of the public. The compliance point for the surface worker is the Training Building. The compliance point for the underground worker is downwind from the waste during initial emplacement in a room. The compliance point for the member of the public is the nearest point outside the controlled area where ranch hands may be working.

HEALTH BASED LEVELS The environmental performance standard proposed for the workers was the Occupational Safety and Health Administration (OSHA) 8-hour time weighted average (TWA) for each compound. The environmental performance standards proposed for the public were 10^{-6} for Class A and B2 carcinogens and 10^{-5} for Class C carcinogens and a Hazard Quotient of 1 for non-carcinogens. These are summarized in Table 7.

TABLE 7 Risk Levels Proposed in the WIPP RCRA Part B Permit Application in 1996 (Appendix D9, Tables D9-5, -6, -8, and -9)

EXPOSED CLASS	COMPLIANCE POINT	CLASS A and B2 CARCINOGENS	CLASS C CARCINOGENS	NON-CARCINOGENS
Surface Worker	Training Building	OSHA 8-HOUR TWA		
Underground Worker	Exhaust drift adjacent to filled room	OSHA 8-HOUR TWA		
Public	Controlled area fence line	10^{-6}	10^{-5}	1

These risk levels were not used by the New Mexico Environment Department (NMED) to develop the standards that eventually were included in the Hazardous Waste Facility Permit (Permit) that was issued in 1999. The NMED reduced the standards to only two receptors: the Underground Worker and the Surface Worker. These standards which are reflected in the VOC limits in the Permit are listed in Table 8.

TABLE 8 Risk Levels Imposed by the NMED in the Permit in 1999

EXPOSED CLASS	COMPLIANCE POINT	CLASS B2 CARCINOGENS	CLASS C CARCINOGENS	NON-CARCINOGENS
Surface Worker	Training Building	10^{-5}	10^{-5}	1
Underground Worker	Exhaust drift adjacent to filled room	OSHA IDLH or LFL	OSHA IDLH or LFL	OSHA IDLH or LFL
Public	Controlled area fence line	Bounded by Surface Worker Limit		

IDLH = Concentration that is immediately dangerous to life and health
LFL = Lower flammability limit

The NMED translated these risk levels into specific concentrations of concern (Cs of C) for each VOC and published them as repository limits and room-based limits. Action levels associated with these limits were also established in the Permit. The NMED modeled cumulative risk and hazard due to exposure to all compounds simultaneously. This required them to develop a process for translating the total risk into a specific risk associated with each VOC involved. The rationale used is documented in a memorandum to file issued by the NMED in 1998 (Zappe, 1998) and in written testimony submitted at the 1999 Permit Hearing (New Mexico Environment Department, 1999). The NMED accepted the Permittees limited list of analytes (which constituted 99 percent of the risk or hazard) and apportioned risk among the nine compounds. This risk apportionment has been modified over time. The most recent apportionment is shown in Table 8, along with the percentage of the total risk assigned to the compound. Table 9 focuses on repository limits since room-based limits are now monitored separately using a Disposal Room VOC Monitoring System.

TABLE 9 Repository Limits for Specific Compounds and their Related Risk Portions

VOC OF INTEREST	TYPE	LIMIT IN PERMIT (ppbv)	ASSOCIATED RISK	ASSOCIATED HAZARD	PERCENT OF TOTAL RISK	PERCENT OF TOTAL HAZARD
Carbon Tetrachloride	C	960	4.3E-06		44.6	
Chlorobenzene	N	220		2.4E-03		88.5
Chloroform	C	180	2.4E-06		24.9	
1,1-Dichloroethene	N	100		2.3E-04		8.7
1,2-Dichloroethane	C	45	5.6E-07		5.8	
Methylene Chloride	C	1,930	1.9E-08		0.2	
1,1,2,2-Tetrachloroethane	C	50	2.3E-06		24.5	
Toluene	N	190		1.2E-04		4.4
1,1,1-Trichloroethane	N	590		7.6E-05		2.8
		TOTAL	9.6E-6	2.7E-3	100 %	100 %

C = Carcinogen
N = Non-carcinogen

The limit represents a concentration measured in the underground at Station VOC-A.

In the design of the current Panel Closure, performance criteria were established in the form of health based levels (HBLs) that could be applied at any appropriate point of compliance (the Land Withdrawal boundary was used in the Panel Closure design document titled *Conceptual Design for Operational Phase Panel Closure Systems,* Appendix I1 of the 1996 Permit Application (U. S. Department of Energy, 1996 a)). This approach was driven by the no-migration standard found in 40 CFR 268 which applied at the time. The methodology for calculating HBLs that was used was described in the proposed ruling on Subpart S, Corrective Action for Solid Waste Management Units at Hazardous Waste Management Facilities (Federal Register, 1990).

In the proposed 40 CFR 264 Subpart S, the action levels, or HBLs, are calculated given the exposure assumptions for the media of interest and the toxic or carcinogenic effects for each hazardous constituent. The proposed Subpart S recommended that continuous lifetime exposure duration of 70 years be assumed; however, because the operational/closure phase of the facility is 35 years, a 35-year exposure is assumed in determining HBLs for the assessment. The assumed risk levels for carcinogens are 10^{-6} for Class A or B2 carcinogens and 10^{-5} for Class C carcinogens. In determining HBLs for non-carcinogens, the chemical-specific reference concentrations are used, which estimate the daily exposure an individual can experience without appreciable risk of adverse effects during a lifetime. Because the guidelines refer to excess health risks, the calculated HBLs are applied only to potential migration of hazardous constituents from the disposed waste.

The methodology for determining HBLs is derived from the EPA's Risk Assessment Guidance for Superfund (U. S. Environmental Protection Agency, 1989). Although the EPA provides alternate "standard default exposure factors," exposure assumptions outlined in the proposed Subpart S were used.

To calculate the HBLs in air for carcinogens with an absorption factor conservatively assumed to be

equal to 1, the following equation is used:

$$\text{HBL} = \frac{\text{TRL} \times \text{AT} \times \text{EF} \times \text{ED}}{\text{IUR}}$$

where:

HBL = HBL for carcinogen, $\mu g/m^3$
TRL = target risk level (TRL), 10^{-5} (Class C) or 10^{-6} (Class A and B2)
AT = averaging time, 25,550 days for carcinogens (70 years × 365 days/year)
EF = exposure frequency, 365 days/year
ED = exposure duration, 35 years
IUR = inhalation unit risk factor (IUR) for carcinogen, $(\mu g/m^3)^{-1}$

For non-carcinogens, the HBLs in air are calculated as follows:

$$\text{HBL} = \frac{\text{THQ} \times \text{RfC} \times \text{AT}_P \times \text{AT}_w \times \text{EF}_p \times \text{EF}_w \times \text{ED}_p \times \text{ED}_w}{\text{AT}_P \times \text{AT}_w \times \text{EF}_p \times \text{EF}_w \times \text{ED}_p}$$

where:

HBL = HBL for non-carcinogen, $\mu g/m^3$
THQ = target hazard quotient (THQ), assumed to be 1
RfC = reference concentration for the non-carcinogen, mg/m^3
AT_P = averaging time, 12,775 days for non-carcinogenic exposure for public (ED × 365 days/year)
AT_w = averaging time, 87,600 for non-carcinogenic exposure for non-waste surface workers based on exposure duration)
EF_p = exposure frequency for public, 365 days/year
EF_w = exposure frequency for non-waste surface worker, 1,920 hours/year
ED_p = exposure duration for public, 35 years
ED_w = exposure duration, non-waste surface worker, 10 years.

The derivation of both of these equations can be found in DOE/CAO-96-2160, Chapter 5 (U. S. Department of Energy, 1996 b).

The toxicity measures (i.e., IURs and reference concentrations [RfCs]) used in the calculations are presented in Table 10. The main source of these data is the EPA Integrated Risk Information System (IRIS); the data in the IRIS system are updated monthly and are reviewed and approved by the EPA. Values not in the IRIS system are based on EPA recommended sources. This list has been updated from the original study in the Permit Application.

TABLE 10: EPA Risk Factor for Volatile Organic Compounds (as of 4/2/2012)

o-Xylene	---	1.00E-01

--- No data/not classifiable/inadequate data

In calculating the HBLs for both carcinogens and non-carcinogens, exposure duration of 35 years was assumed for the public and 10 years for the non-waste surface worker. For non-carcinogens, the averaging time is equivalent to the exposure duration; therefore, this assumption has no effect on the calculated value of the HBL. This assumption is reasonable, because waste emplacement is expected to last 25 years, and a ten-year closure period follows. For the non-waste surface worker, the assumption is based on an employment period of 10-years at 40 hours per week for 48 weeks per year in the Training Building. The averaging time for carcinogens is 70 years, consistent with EPA guidance. The calculated HBL for each indicator VOC in air is listed in Table 11. Values are shown for two risk levels.

The public risk is 10^{-6} and the surface worker risk is 10^{-5}. The original Panel Closure design uses the public risk values.

TABLE 11: Health Based Levels for various Risk Scenarios

VII. SAMPLE CALCULATION

Table 12 provides the expected emission rates for the following:

- Drum
- Open room
- Closed room
- Open panel (with 6 filled rooms and 1 open room)
- Closed panel
- Repository (9 closed panels, one open panel with 6 closed rooms and one open room)

The following assumptions are used:

- Recalculated source term (Table 1)
- Containers have filters with the repository average H_2 diffusion rate of 1.25×10^{-5} mole/s/mole fraction installed (Table 3)
- Effective gas generation rate of 0.5 mole/drum/year (Table 4)
- 4,777 drums containing 6,050 filters per room (Table 5)
- There is no ventilation leakage through closed areas.

The term "average" is used to indicate that the source term is the weighted average concentration. The term "maximum" is used to describe the repository emission rate, since the calculation is for a full repository with one open panel containing a full open room and 6 filled rooms that are isolated from the ventilation.

Concentrations at the receptor points on the surface can be calculated by applying the ADFs in Table 6. The results are shown in Table 13 as a fraction of the HBLs for each compound. The totals show that the HBLs are not exceeded for a repository filled with TRU mixed waste at the weighted average VOC concentrations. The total risk line in Table 13 can be viewed as the compliance margin for each receptor location.

RECALCULATION OF THE VOLATILE ORGANIC COMPOUND SOURCE TERM

by

Robert F Kehrman

RECALCULATION OF THE VOLATILE ORGANIC COMPOUND SOURCE TERM

The volatile organic compound (VOC) source term that was used in the Resource Conservation and Recovery Act (RCRA) no- migration variance petition (NMVP)[1] and the Part B Permit Application[2] was based on the headspace gas samples taken from 930 drums of waste stored at the Idaho National Laboratory and the Rocky Flats Plant. These containers represented the entire spectrum of transuranic (TRU) waste that was expected to be shipped to the Waste Isolation Plant (WIPP) with the exception of the soils waste form. The measured concentrations were accumulated by "Waste Matrix Code Group" (WMCG), which is nomenclature used to express the physical form of the waste. The following WMCGs were used: Combustible waste, Filter waste, Graphite waste, Heterogeneous waste, Inorganic non-metal waste, Lead/cadmium metal waste, Salt waste, Soils, Solidified inorganic waste, Solidified organic waste, Uncategorized metal waste, and Unknown waste. In order to extend the data from the 930 containers to the entire inventory of WIPP-bound waste, a weighting scheme was developed. The TRU Waste Baseline Inventory Report (TWBIR) was used to determine the then current and projected inventory of TRU waste in each of the WMCGs. This information was tabulated (Table C2-2 in the NMVP Appendix WAP). Since the total volume of stored and projected waste did not add up to the approved inventory limit for the WIPP facility, the quantities were scaled up so that the total added up to the approved limit. A weighting factor was then calculated which represented the percentage of each of the WMCGs in the total (scaled inventory).

In order to calculate the source term, the average concentration of each VOC had to be weighted for each WMCG and then summed. This is represented by the following equation:

$$\bar{X} = \sum_{j=1}^{t} w_j * \bar{x}_j$$

where,

$\bar{X} = weighted\ average$
$\bar{x}_j = average\ concentration\ for\ WMCG\ j$
$w_j = weighting\ factor\ for\ WMCG\ j$
$t = number\ of\ WMCG\ s$

and $\bar{x}_j$ is calcualted by:

$$\bar{x}_j = \frac{1}{n_j} * \sum_{j=1}^{n_j} x_{jk}$$

where,

[1] DOE/CAO-96-2160 (Appendix WAP, Appendix VOC)
[2] DOE/WIPP 91-005, Rev. 6 (Appendix C2, Appendix D13)

n_j = number of samples in $WMCG\ j$
x_{jk} = analysis *k* for $WMCG\ j$.

The new calculations use over 136,000 sample results collected from TRU waste prior to shipment to the WIPP facility. These analyses were conducted in accordance with the WIPP Permit. Prior to October 2006, analyses were required on 100 percent of the containers. After this time, only representative sampling was required resulting in fewer sampled per waste stream.

The process for developing the new source term is as follows:

Step 1—a data dump of all headspace gas measurements was obtained from the WIPP Waste Information System beginning with the first shipment in 1999 through October 6, 2010. The data were provided as concentrations in parts per million by volume (ppmv) for each VOC plus hydrogen and methane for each container.

Step 2—the data were separated by year in order to provide manageable record sizes.

Step 3—measurements that were shown with a "U" flag were undetected. The values shown represent the method detection limit. These values were divided by 2 prior to including them in the total.

Step 4—each container was assigned to a WMCG based on the TRUCON code. During this process, 71 RH waste containers included in the database were removed (TRUCON codes beginning with a "3").

Step 5—the data were sorted by WMCG.

Step 6—the number of measurements for each VOC was determined for each WMCG using the "COUNT" function in Excel.

Step 7—the concentrations were summed

Step 8—the sum was divided by the number of samples to determine the average concentration for each VOC for each WMCG. Because there is a spreadsheet for each year, the yearly totals and counts were rolled up to a single table and then re-averaged for each WMCG and each VOC. Attachment A contains the averages for each year for each WMCG. The rollup is on the last page.

Step 9—the average concentrations for each compound and each WMCG was multiplied by the weighting factor to simulate the average concentration for each VOC in a full repository. This is shown in Attachment B. The following is an explanation of the different sets of concentrations in Attachment B.

Three sets of calculations are provided in Attachment B. All three use the measured repository headspace data from Attachment A. The first set of calculations uses the 2004 Compliance Recertification Application inventory projections for determining the weighting factors.[3] The results of

[3] Title 40 CFR Part 191 Subparts B and C Compliance Recertification Application 2004 March 2004 DOE/WIPP 2004-3231, Appendix DATA, Attachment F

this evaluation should be used in the Risk Screening exercise to determine the VOCs that make up 99 percent of the risk. The second set uses the same weighting factors that were used in the Permit Application and the NMVP. However, the results of the 930 drum sampling campaign is replaced with the new sampling results. This provides a comparison of the original assumptions regarding the VOC source term and the actual results. The third set of calculations modifies the Permit Application and NMVP weighting factors in two ways. The total volume of waste to be disposed is set by the Land Withdrawal Act (LWA) (which was not considered in the original scaling), so the total waste was adjusted to the LWA limits. Second, the original scaling appears to contain some unspecified factor for each WMCG that affected the scaled result. This was changed to a linear scaling of the total stored and projected waste. This resulted in slightly different weighting factors.

Note that the last page in Attachment B compares the various calculations of weighted VOC concentrations to the original source term.

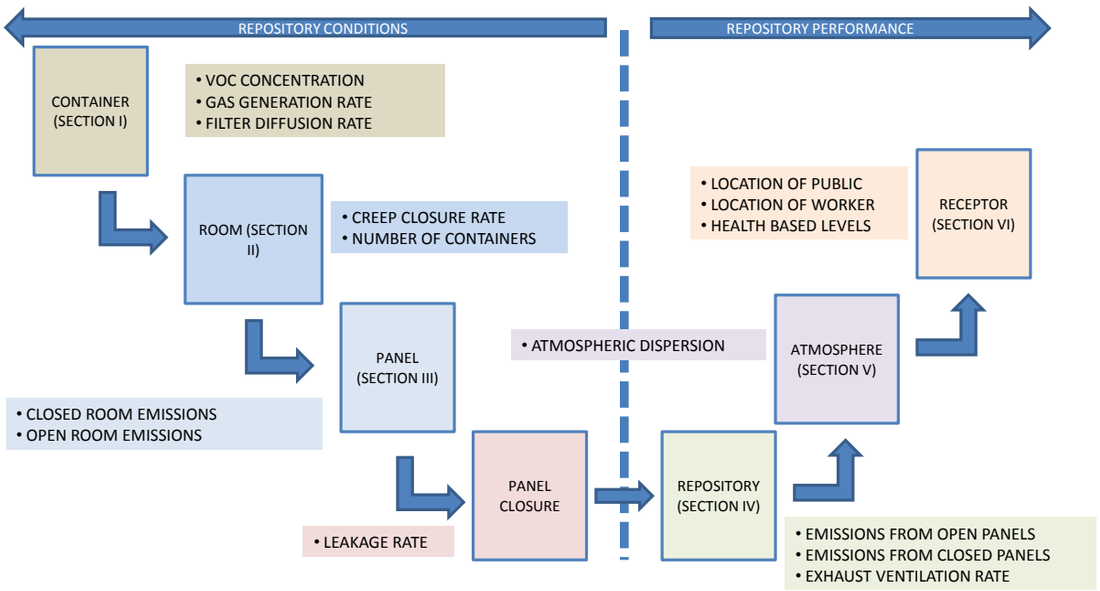
CALCULATIONS TO SUPPORT PANEL CLOSURE DESIGN PAPER 8 29 12

Figure 1 is a block diagram of the elements that go into preparing a risk model to demonstrate operational impacts due to emissions from the Waste Isolation Pilot Plant repository. The goal of this discussion is to provide information needed to specify the design of the Panel Closure which will serve to assure the performance standards to the right on the diagram are met for the conditions in the repository shown on the left in Figure 1. When the original Part B Permit Application for the Waste Isolation Pilot Plant (WIPP) (U. S. Department of Energy, 1996 a) facility was submitted in 1996, one of the design parameters for Panel Closure was that "the panel closure system shall limit the migration of [volatile organic compounds] VOCs to the compliance point so that compliance is achieved by at least one order of magnitude." This criterion has been changed for the current design to only require compliance without an additional compliance margin. The following discusses each element in the order indicated by the Roman Numerals on the Figure.

FIGURE 1: Elements of the Waste Isolation Pilot Plant Air Exposure Pathway



VOC CONCENTRATION	is in Sheet *Weighted HS Conc*
GAS GENERATION RATE	is in Sheet *Inputs and Outputs*
FILTER DIFFUSION RATE	is in Sheet *Filter Information and Inputs and*
CREEP CLOUSRE RATE	is in Sheet *Inputs and Outputs*
NUMBER OF CONTAINERS	is in Sheet *Containers*
LEAKAGE RATE	is in Sheet *Leakage* , however it is not considered in the Panel Closure Paper.
EMISSIONS FROM OPEN PANELS	is in Sheet *Inputs and Outputs*
EMISSIONS FROM CLOSED PANELS	is in Sheet *Inputs and Outputs*
EXHAUST VENTILATION RATE	is in Sheet *Inputs and Outputs*
ATMOSPHERIC DISPERSION	is in Sheet *Risk Factors, ADFs and HBLs*
LOCATION OF THE WORKER	is in Sheet *Risk Factors, ADFs and HBLs*
LOCATION OF THE PUBLIC	is in Sheet *Risk Factors, ADFs and HBLs*
HEALTH BASED LEVELS	is in Sheet *Risk Factors, ADFs and HBLs*

The following is from Section 1 of the paper: "ESTABLISHING VOLATILE ORGANIC COMPOUND LIMITS FOR THE PANEL CLOSURE DESIGN". VOC CONCENTRATION Information needed on the container scale for air dispersion modeling is the average concentration of VOCs in the headspace of the container which defines the release source term and the gas generation rate which is a driving force to move VOCs from closed rooms and panels into the repository ventilation system. The VOC source term used for the original Panel Closure design effort was developed based on a limited sampling program conducted in Idaho and at Rocky Flats. Subsequent to that time, a weighted average source term was developed using the same data, however, a weighting process was developed to accommodate the wide variety of waste forms and to weight them in accordance with their prevalence. The process for developing the weighted average source term is described in Appendix C2 of the 1996 Permit Application (U. S. Department of Energy, 1996 a). The results are summarized in Table 1. In 2010, the source term was revised using the same methodology; however, over 130,000 headspace gas measurements were available (Kehrman, 2011). The revised source term is shown in Table 1. The values in Table 1 represent the average concentration that would be expected in a filled, closed room.

THESE VALUES COME FROM A SHEET TITLED "HSGD ROLLUP 11- 21 2011 CORRECTED FILE"

FILTER DIFFUSION RATE The rate at which VOCs will be emitted from containers is a function of the diffusion rate for the individual filter on the containers. These filters are placed on every container to prevent the buildup of hydrogen as the result of radiolysis. Diffusion is relevant for open rooms only. Closed rooms are assumed to be in equilibrium with the average VOC concentration in the containers. Container filters are specified with a hydrogen diffusion rate. The methodology for calculating the VOC diffusion rate based on the hydrogen rate is given in Chapter 5 of the 1996 No-Migration Variance Petition (U. S. Department of Energy, 1996 b).

This sheet contains input values taken for the analytes of interest. (Rows 15 to 50) The headspace concentration value are the revised weighted average which is an update to the values in the Permit Application in 1995. The diffusivity numbers are copied from column H and were calculated using the following formula from the Permit Application. Critical values were taken from compound specific searches of the Internet.

$$\frac{D_{VOC-air}}{D_{H_2-air}} = \left(\frac{P_{c,VOC}}{P_{c,H_2}}\right)^{1/3} \times \left(\frac{T_{c,VOC}}{T_{c,H_2}}\right)^{5/12} \times \left[\frac{\left(\frac{1}{MW_{air}} + \frac{1}{MW_{VOC}}\right)}{\left(\frac{1}{MW_{air}} + \frac{1}{MW_{H_2}}\right)}\right]^{1/2}$$

Compound	Mol Wt	Headspace Concentration (ppmv)	Diffusivity VOC-air (298.15 K, 1 atm)	Tc (K)	Pc (bar)	Pc (atm)	Diffusivity for specific compound (Use Permit Formula)

GAS GENERATION Appendix D11 of the 1996 Permit Application (U. S. Department of Energy, 1996 a) includes information on gas generation by WIPP waste. Of the gas-generating mechanisms described in Appendix D11, microbial degradation will contribute the most to the generation rate during the time periods of interest. The best estimate for gas generation from microbial degradation under humid conditions is 0.1 moles of gas per drum per year. Although Appendix D11 states that the maximum expected value for any one drum of waste is 0.4 moles per drum per year, the lowest expected value for any one drum is 0 moles per drum per year. A discussion of the relationship between gas generation, brine inflow, and creep closure can be found in Section I-1e(4). In reality, under the conditions that will initially exist in a closed panel, the predominant degradation mechanisms may consume gas at a rate faster than it is produced. This outcome is a function of the availability of nutrients to sustain microbial activities. Indications of gas consumption activities are in Francis and Gillow (Francis, A.J. and J.B. Gillow, 1994), where they reported 200-day experiments (see Appendix D11).

CREEP CLOSURE RATE The average creep closure rate will result in a reduction of the panel void volume of 812 m^3 per year for each panel. Calculations in Appendix D9 of the 1996 Permit Application (U. S. Department of Energy, 1996 a) convert this rate at which air is "squeezed" out of the room to an equivalent gas generation rate of 0.4 moles/drum/year.

EFFECTIVE GAS GENERATION RATE: The Effectve Gas Generation Rate is the Gas generation rate plus the Creep closure Rate converted to moles/drum/year.

These factor are as follows: For exposure to cancer causing compounds, the receptor is a member of the public. The exposure is 24 hours per day for 35 years. The exposure is averaged over 70 year lifetime. For exposure to non cancer causing compounds, the public receptor is exposed for 24 hours per day for 35 years and the exposure is averaged of the the duration of the exposure (35 years); for the worker inthe training building, the exposure is for 40 hours per week for 48 weeks per year for ten years and the exposure is averaged of the the duration of ten years.

THESE ARE THE FORMULAE USED IN THE CALCULATIONS. SEE THE NARRATIVE FOR FURTHER EXPLANATION.

HS_{VOC}

$MF_{VOC} = (HS_{VOC}) \times (10^{-6} \text{ mole fraction/ppmv})$

$D_{VOC} = \left(\frac{D_{VOC-air}}{D_{H_2-air}}\right) \times D_{H_2}$

$ADE = D_{VOC} \times MF_{VOC} \times 31{,}536{,}000 \text{ s/year}$

OPEN ROOM EMISSIONS The open room emission rate is dependent on the number of drums that have been emplaced in the room and the diffusion of VOCs across the drum vent filters. Assuming a continuous fresh air flow across the filters, VOCs will diffuse from the drums at a rate that is dependent on the concentration gradient across the filters and the diffusion properties of the VOCs. The open room emission rate is calculated using the equation below:

$AORE_{VOC} = ADE_{VOC} \times nD$

EMISSIONS FROM CLOSED ROOMS Using this effective gas generation rate for a room of containers that has the ventilation barrier in place, the closed room emission rate for each VOC is calculated as shown below:

$ACRE_{VOC} = (GR) \times (11{,}571 \text{ drum/roompanel}) \times MF_{VOC}$

EMISSIONS FROM OPEN PANELS The open panel emission rate for each VOC is based on the number of full rooms, the number of drums in the open room, and the emission rates from each type of room. This can be calculated as shown below:

$AOPE_{VOC} = (R_o \times AORE_{VOC}) + (R_{cr} \times ACRE_{VOC})$

EMISSIONS FROM CLOSED PANELS Volatile organic compounds will diffuse from the drums at a rate dependent on the concentration gradient across the filters. As the concentration gradient decreases, the diffusion rate of each VOC decreases. After a panel is closed, fresh air will no longer flow across the waste drums, and VOC concentrations in the air space above the filter will begin to build up and approach the concentrations in the drum headspace. Therefore, the concentration of VOCs that would be present in the panel atmosphere would be equivalent to the average drum headspace concentration. For a closed panel of N drums, the closed panel emission rate for each VOC is calculated as shown below:

$ACPE = (GR) \times (81{,}000 \text{ drums/panel}) \times MF_{VOC}$

The emission rate from the repository can then be calculated as the sum of the open panel and closed panel rates as folllows:

$EC_{VOC} = P_O \times AORE_{VOC} + P_C \times ACPE_{VOC}$

MW_{VOC}

$ER_{VOC} = EC_{VOC} \times MW_{VOC}/(454 \times 2{,}000)$

$ER_{VOC} = ER_{VOC} \times 2{,}000/(365 \times 24)$

This value (SXPE) is calculated by multiplying AOPE times the molecular weight times 1,000,000 micrograms per gram and dividing by the E-300 ventilation rate (260,000 scfm) times 525,600 minutes per year times 0.0283 cubic meters per cubic foot

This value (SCPE) is calculated by multiplying AOPE times the molecular weight times 1,000,000 micrograms per gram and dividing by the E-300 ventilation rate (260,000 scfm) times 525,600 minutes per year times 0.0283 cubic meters per cubic foot

This value is the concentration at VOC A and is SXPE plus 9 times SCPE

This value is the concentration at VOC A and is SXPE plus 9 times SCPE in ppbv

This is the concentration at VOC A for a full repository normalized to the ventilation rates assumed when the concentrations of concern were calculated (425,000 and 130,000).

FILTER DIFFUSION RATE The rate at which VOCs will be emitted from containers is a function of the diffusion rate for the individual filter on the containers. These filters are placed on every container to prevent the buildup of hydrogen as the result of radiolysis. Diffusion is relevant for open rooms only. Closed rooms are assumed to be in equilibrium with the average VOC concentration in the containers. Container filters are specified with a hydrogen diffusion rate. The methodology for calculating the VOC diffusion rate based on the hydrogen rate is given in Chapter 5 of the 1996 No-Migration Variance Petition (U. S. Department of Energy, 1996 b).

	Filters per container			1.26676083				

NUMBER OF CONTAINERS The original assumption was that each Panel would contain 81,000 containers. This number is important because emissions are related to the filter diffusivity associated with each container; therefore the number of filters emitting VOCs to a room that is being filled is part of the calculation of releases. Closed rooms are unventilated and are conservatively assumed to be at the average concentration of the containers that were disposed and emissions are only related to the gas generation rate and creep closure rate (i.e., equivalent gas generation rate). The following is a compilation of the number of containers disposed by Panel, inlcuding Room 7 of Panel 6. A room is considered to have 567 linear feet of disposal space. Since Room 1 only has 367 feet (i.e., no waste is placed in the intake or exhaust drifts, a full panel is considered to have 6.7 Rooms

ATMOSPHERIC DISPERSION This section presents the results of air dispersion modeling performed inside and outside the WIPP site boundary. The modeling was performed to evaluate four specific scenarios: the Boundary Public, Livingston Ridge Rancher (grazing allotment on the north side of the WIPP site), Antelope Ridge Rancher (grazing allotment on the south side of the WIPP site), and Surface Worker. The Long-Term Version of the Industrial Source Complex (ISCLT3) model, (U.S. Environmental Protection Agency, 1995), was used for the original air dispersion modeling. Concentrations were modeled in accordance with (U.S. Environmental Protection Agency, 1992) EPA (1992). Details of the modeling are described in Appendix D10 of the 1996 Permit Application. The modeling produced the air dispersion factors (ADFs) listed in the center column of Table 6. In 2010 the modeling was updated in order to use newer EPA analytical tools (AERMOD) and updated physical conditions (new buildings, three exhaust stacks) (URS Corporation, 2010).

Area	Original Air Dispersion Factor (ADF)	Revised Air Dispersion Factor (ADF)
Training Building	1.23E-02	1.14E-02
Livingston Ridge Allotment	9.80E-05	1.76E-04
Antelope Ridge Allotment	6.70E-05	6.72E-04
WIPP Site Boundary	1.20E-04	8.78E-05

LOCATION OF PUBLIC AND WORKERS Three classes of exposed individuals (receptors) were presented in Appendix D9 of the 1996 Permit Application (U. S. Department of Energy, 1996 a); a surface worker, an underground worker, and a member of the public. The compliance point for the surface worker is the Training Building. The compliance point for the underground worker is downwind from the waste during initial emplacement in a room. The compliance point for the member of the public is the nearest point outside the controlled area where ranch hands may be working.

HEALTH BASED LEVELS The environmental performance standard proposed for the workers was the Occupational Safety and Health Administration (OSHA) 8-hour time weighted average (TWA) for each compound. The environmental performance standards proposed for the public were 10^{-6} for Class A and B2 carcinogens and 10^{-5} for Class C carcinogens and a Hazard Quotient of 1 for non-carcinogens. These are summarized in Table 7. These risk levels were not used by the New Mexico Environment Department (NMED) to develop the standards that eventually were included in the Hazardous Waste Facility Permit (Permit) that was issued in 1999. The NMED reduced the standards to only two receptors: the Underground Worker and the Surface Worker. These standards which are reflected in the VOC limits in the Permit are listed in Table 8. The NMED translated these risk levels into specific concentrations of concern (Cs of C) for each VOC and published them as repository limits and room-based limits. Action levels associated with these limits were also established in the Permit. The NMED modeled cumulative risk and hazard due to exposure to all compounds simultaneously. This required them to develop a process for translating the total risk into a specific risk associated with each VOC involved. The rationale used is documented in a memorandum to file issued by the NMED in 1998 (Zappe, 1998) and in written testimony submitted at the 1999 Permit Hearing (New Mexico Environment Department, 1999). The NMED accepted the Permittees limited list of analytes (which constituted 99 percent of the risk or hazard) and apportioned risk among the nine compounds. This risk apportionment has been modified over time. The most recent apportionment is shown in Table 8, along with the percentage of the total risk assigned to the compound. Table 9 focuses on repository limits since room-based limits are now monitored separately using a Disposal Room VOC Monitoring System. In the design of the current Panel Closure, performance criteria were established in the form of health based levels (HBLs) that could be applied at any appropriate point of compliance (the Land Withdrawal boundary was used in the Panel Closure design document titled Conceptual Design for Operational Phase Panel Closure Systems, Appendix I1 of the 1996 Permit Application (U. S. Department of Energy, 1996 a)). This approach was driven by the no-migration standard found in 40 CFR 268 which applied at the time. The methodology for calculating HBLs that was used was described in the proposed ruling on Subpart S, Corrective Action for Solid Waste Management Units at Hazardous Waste Management Facilities (Federal Register, 1990). In the proposed 40 CFR 264 Subpart S, the action levels, or HBLs, are calculated given the exposure assumptions for the media of interest and the toxic or carcinogenic effects for each hazardous constituent. The proposed Subpart S recommended that continuous lifetime exposure duration of 70 years be assumed; however, because the operational/closure phase of the facility is 35 years, a 35-year exposure is assumed in determining HBLs for the assessment. The assumed risk levels for carcinogens are 10^{-6} for Class A or B2 carcinogens and 10^{-5} for Class C carcinogens. In determining HBLs for non-carcinogens, the chemical-specific reference concentrations are used, which estimate the daily exposure an individual can experience without appreciable risk of adverse effects during a lifetime. Because the guidelines refer to excess health risks, the calculated HBLs are applied only to potential migration of hazardous constituents from the disposed waste. The methodology for determining HBLs is derived from the EPA's Risk Assessment Guidance for Superfund (U. S. Environmental Protection Agency, 1989). Although the EPA provides alternate "standard default exposure factors," exposure assumptions outlined in the proposed Subpart S were used. To calculate the HBLs in air for carcinogens with an absorption factor conservatively assumed to be equal to 1, the following equation is used:

and reference concentrations (RfCs)) used in the
ble 10. The main source of these data is the EPA
tem (IRIS); the data in the IRIS system are updated
approved by the EPA. Values not in the IRIS system are
urces. This list has been updated from the original study

$$HBL = \frac{TRL \times AT}{EF \times ED \times IUR}$$

where:

HBL	=	HBL for carcinogen, $\mu g/m^3$
TRL	=	target risk level (TRL), 10^{-5} (Class C) or 10^{-6} (Class A and B2)
AT	=	averaging time, 25,550 days for carcinogens (70 years × 365 days/year)
EF	=	exposure frequency, 365 days/year
ED	=	exposure duration, 35 years
IUR	=	inhalation unit risk factor (IUR) for carcinogen, $(\mu g/m^3)^{-1}$

For non-carcinogens, the HBLs in air are calculated as follows:

$$HBL = \frac{THQ \times RfC \times AT_{p\,or\,w} \times (1{,}000\,\frac{\mu g}{mg})}{EF_{p\,or\,w} \times ED_{p\,or\,w}}$$

where:

HBL	=	HBL for non-carcinogen, $\mu g/m^3$
THQ	=	target hazard quotient (THQ), assumed to be 1
RfC	=	reference concentration for the non-carcinogen, mg/m^3
AT_p	=	averaging time, 12,775 days for non-carcinogenic exposure for public (ED × 365 days/year)
AT_w	=	averaging time, 87,600 for non-carcinogenic exposure for non-waste surface workers based on exposure duration)
EF_p	=	exposure frequency for public, 365 days/year
EF_w	=	exposure frequency for non-waste surface worker, 1,920 hours/year
ED_p	=	exposure duration for public, 35 years
ED_w	=	exposure duration, non-waste surface worker, 10 years.

cinogens and non-carcinogens, exposure duration of 35 years
years for the non-waste surface worker. For non-carcinogens,
the exposure duration; therefore, this assumption has no effect
This assumption is reasonable, because waste emplacement is
-year closure period follows. For the non-waste surface
an employment period of 10 years in the training building.
or VOC in air is listed in Table 11. Values are shown for two
d the surface worker risk is 10^{-5}. The original Panel Closure

IUR = Inhalation unit risk factor (IUR) for carcinogen, $(\mu g/m^3)^{-1}$

For non-carcinogens, the HBLs in air are calculated as follows:

$$HBL = \frac{THQ \times RfC \times AT_{p\,or\,w} \times (1{,}000\ \frac{\mu g}{mg})}{EF_{p\,or\,w} \times ED_{p\,or\,w}}$$

where:

HBL = HBL for non-carcinogen, $\mu g/m^3$
THQ = target hazard quotient (THQ), assumed to be 1
RfC = reference concentration for the non-carcinogen, mg/m^3
AT_p = averaging time, 12,775 days for non-carcinogenic exposure for public (ED x 365 days/year)
AT_w = averaging time, 87,600 for non-carcinogenic exposure for non-waste surface workers based on exposure duration)
EF_p = exposure frequency for public, 365 days/year
EF_w = exposure frequency for non-waste surface worker, 1,920 hours/year
ED_p = exposure duration for public, 35 years
ED_w = exposure duration, non-waste surface worker, 10 years.

The toxicity measures (i.e., IURs calculations are presented in Ta Integrated Risk Information Syst monthly and are reviewed and u based on EPA recommended so in the Permit Application.

In calculating the HBLs for both car was assumed for the public and 10 the averaging time is equivalent to on the calculated value of the HBL. expected to last 25 years, and a ter worker, the assumption is based or The calculated HBL for each indicat risk levels. The public risk is 10^{-6} an design uses the public risk values.

SAND83-1908

Reference Stratigraphy and Rock Properties for the Waste Isolation Pilot Plant (WIPP) Project

R. D. Krieg
Sandia National Laboratories
Albuquerque, New Mexico 87185

ABSTRACT

A stratigraphic description of the country rock near the working horizon at the Waste Isolation Pilot Plant (WIPP) is presented along with a set of mechanical and thermal properties of materials involved. Data from 41 cores and shafts are examined. The entire stratigraphic section is found to vary in elevation in a regular manner, but individual layer thicknesses and relative separation between layers are found to have no statistically significant variation over the one mile north to south extent of the working horizon. The stratigraphic description is taken to be relative to the local elevation of Anhydrite b. The material properties have been updated slightly from those in the July '81 Reference Stratigraphy. This reference stratigraphy/properties document is intended primarily for use in thermal/structural analyses. This document supercedes the July '81 stratigraphy/properties document.

ACKNOWLEDGEMENT

I wish to thank many people who have contributed to this report. I thank Dale Roberts and others at Bechtel as well as Dale Stephenson and others at TSC/D'Appolonia who helped formulate the stratigraphy, proofed an early rough draft and made many valuable suggestions. I also thank Darrell Munson, Hal Morgan, Linda Branstetter, Mike Stone, Wolfgang Wawersik and Rudy Matalucci for proofing, pointing out errors, and suggesting improvements. Finally, I thank Nancy Moore for typing and assembling the report and for patience through all the revisions.

I. INTRODUCTION

There are many structural analysts in several organizations who have been and presently are performing thermal/structural analyses of shafts, drifts, and rooms at the WIPP site. The details of the stratigraphy and materials have been found to be important in these analyses. Rather than have each analyst build a model of his/her own, it was decided in mid 1979 to study the available data and collectively decide on an appropriate reference model of the stratigraphy and a set of materials properties. The initial reference set was particularly valuable since only cores and core-hole logs were available at that time to define the stratigraphy and the interpretation of these was subjective so that choice of a set required some judgement. Analysts, geologists, geophysicists, and mining engineers all had useful inputs to interpretation of the data and definition of a reference stratigraphy/properties. It was recognized from the outset that this reference set must be updated as new data became available. These updates could hopefully be made in a controlled manner so that analysts could always use a reference set without having to use ad hoc modifications to the reference with a different set of modifications used by each organization or analyst.

Early work on a reference stratigraphy was documented in internal memos [1,2] at Sandia National Laboratories. There were probably similar memos written by structural analysts in other companies associated with the WIPP. A meeting was held on November 15, 1979, with attendees from WPO/DOE, Bechtel, the TSC/D'Appolonia, and Sandia, and the first reference stratigraphy and properties were set down [3,4,5]. This was then declared by the project office to be used for all structural calculations[6]. It was called the "November '79 Reference Stratigraphy" and was used for some time [7].

The November '79 Reference Stratigraphy was updated in July, 1981, when more data became available [8]. The material properties in particular were revised at that time. Since this was prior to construction of the shafts, no attempt was made to revise the stratigraphy. This document was used [9,10] as the reference until the present time.

When the shafts were constructed and logged, it became apparent that the July '81 Reference Stratigraphy should be updated. Analysts began using updates to the stratigraphy which accounted for new observational data [11]. A meeting was held between analysts, project geologists, and geological properties scientists at Sandia to consider updates to the reference stratigraphy [12]. Because other analysts are involved, it was obvious that a consensus of everyone, not just Sandia, was needed to define a useful reference.

On July 7, 1983, a meeting was held with attendees from Bechtel National, the TSC/D'Appolonia, Sandia National Laboratories, and the DOE/WIPP Project Office. The meeting notice, meeting schedule, and minutes are included in Appendix A. Action items resulting from the meeting and recorded there include clearing up some questions about correlation between the core, core logs, and tests on insolubles content. Another was a bringing together of suggested reference stratigraphies submitted by Bechtel [13] and the TSC/D'Appolonia [14] and Sandia into a documented reference stratigraphy/properties that would be accepted by everyone. This is the resulting reference stratigraphy/properties document.

A suggestion was made at the meeting documented in Appendix A that three stratigraphic descriptions would be useful as noted on page 43. The present document is a combination of two of the suggested models. The third model would cover a 900m (3000 ft) depth and would be used for regional studies. Due to time constraints, this is not covered here.

The present document is not intended to be a final report on this topic. It is expected that as more data become available, then this document will be revised or superceded.

II. INTENT OF REFERENCE STRATIGRAPHY/PROPERTIES

The intent of this report is to set down a consensus stratigraphy and set of material properties which are suitable for structural analyses of the underground WIPP site. The first part is a presentation of the model which is local to the underground WIPP horizon (near a depth of 655 m (2150 ft)), and is to be used for drift and room calculations. Next, the properties of the rocks listed in the stratigraphy are presented which are generally those presented in the July '81 Reference Stratigraphy. The report concludes with a short summary.

III. STRATIGRAPHY

A. Shift in Reference Depth

The stratigraphy near the underground WIPP horizon has been characterized by examining 41 cores and core logs [10(App C,D,E),15]. These cores were taken throughout the site as it existed in the summer of 1983. The locations of the various coreholes [15] are shown in Figure 1. The layers are fairly planar but dip to the south somewhat. This is shown in Figure 2 taken from reference [15]. Stein, Sandia organization 6331, made quantitative tests on the insolubles at various layers in the core from DH 52,53. It was found that visual estimates of the percentages of impurities listed in the core logs were in error. As an action item from the stratigraphic meeting on June 15, 1983, a group of geologists reexamined the core from four boreholes including DH 52,53. With the measured insolubles as a point of reference for visual estimates, the estimates of impurities listed on the core logs were revised. These four revised core logs were then used by Bechtel National [13] and the TSC/D'Appolonia [14] to identify what they felt were the stratigraphic features which are important to structural analyses. The Sandia National Laboratories input was not documented. All three inputs had generally the same features. These features were then identified on all the 41 logs available. The logs were then shifted to a zero level at anhydrite b above the drifts. Anhydrite b was chosen because of its proximity to the drift and its lack of waviness. The height of the various layers above anhydrite b as well as their thicknesses were then listed as shown in Table I.

B. Layer Thicknesses

Average thickness of the anhydrite layers and their standard deviations are listed as entries in Table I. Note the considerable variation in the thicknesses of the anhydrite layers. Fortunately, these variations are not very important in a structural analysis because most of the layers are thin.

Table I. Heights and Thicknesses of Distinct Layers Measured with Respect to the Base of Anhydrite b. All Entries are in Meters

*This includes an adjacent polyhalite layer

The thickness of MB139 is important because of its proximity to the drift and its considerable stiffening effect. It is known to be very non-uniform in thickness as shown in Figure 3 for the variation around the shaft [10(App C)]. Note from the figure that if a small diameter core were to have been taken from the areas shown, the thickness might have been measured as 0.61 m to 1.06 m (2.0 to 3.5 ft) in the exploratory shaft [10(App C, Fig. 4] and from 0.53 m to 1.08 m (1.7 to 3.5 ft) in the ventilation shaft [10(App D)]. The local variation in thickness of MB139 must be averaged out over a considerable bedding area in order to make plane strain drift calculations. The layer thicknesses found from the core are essentially values found at a point in the plan view of the site. In Table II, the average thickness of MB139 and its standard deviation have been determined for the data taken on the two shafts, for the data in Table I, and for two subsets of the Table I data. Note that the average value is not a strong function of north/south position. Note also that as data from larger areas are used, then the standard deviation becomes larger. The relation between standard deviation of the thickness of MB139 S and averaging area A is roughly

$$S = 0.1\ A^{0.06} \qquad (1)$$

where S is in meters and A in square meters. This seems to indicate a long range variation in thickness as well as the short range variation shown in Figure 3. For a 10 m room width, it would not be unreasonable to average the bed thickness over a $400 m^2$ area centered on the drift at the station of interest. The standard deviation expected over this area would be given from Eqn (1) as 0.14 m so that the variation would be roughly that seen in Figure 3. A careful study of the statistics could probably produce an expected average thickness as a function of position over the site. At this point in time, it does not seem reasonable to pursue this approach for three reasons: (i) the confidence in the results would be low because of the small sample size, (ii) it is presently necessary to assume that the thickness variation is isotropic[1] and homogeneous[2], (iii) it appears from Table II that the variation over the site would not be large enough to significantly affect structural behavior of the drifts in any case.

The thickness of MB139 as averaged over a $10\ m^2$ area or larger is a reasonable characterization of the layer in that region. It also appears that layer thicknesses averaged over the entire site are the best values to use at every location on the site. This conclusion is based on the study included as Appendix B. In that study, the thicknesses and relative depths of the anhydrite layers were assumed to vary in a linear manner from north to south. The least square fits to the data, however, showed very little regular variation from north to south. Furthermore, it was found that the variations in the variables were not statistically significant. More concisely, based on the data in Table I, one cannot even determine whether

1. If the shape of the thick and thin places are not generally directional like a plowed field, then the variations are said to be isotropic.

2. If the variation is the same everywhere, i.e., there are no areas which are smoother than others, then it is said to be homogeneous.

TABLE II. VARIATION IN THICKNESS OF ANHYDRITE MB139

Location	Average Thickness (m)	Standard Deviation (m)	Averaged Area (m^2)
Ventilation Shaft	1.06	.15	1.8 m dia = 10.5 m^2
Exploratory Shaft	.85	.11	3.6 m dia = 42. m^2
Entries, Table I	.86	.21	240 x 1540 = 370,000 m^2
S Entries, Tbl. I	.90	.21	55. x 1190 m = 66,000 m^2
N Entries, Tbl. I*	.80	.22	235. x 240 m = 56,000 m^2

*Last eight entries in Table I.

any layer thickens or whether it thins from north to south, much less quantify the variation. Thus, averages of layer thicknesses over the entire site are used here to determine the reference stratigraphy.

The mixed layers are more difficult to identify and abstract for the reference stratigraphy. Some of these layers are present in one core but not the other or they have shifted position with respect to the anhydrite layers. Fortunately, the mixed layers are not adjacent to the drift and it is estimated in the next section that the properties are not drastically different from pure rock salt. Several argillaceous layers are identified near MB138 on the logs from the southern end of the site which have 3-4% clay. Only one smaller thickness layer of this type is seen in the log of D079 taken from the north end. The logs of eight coreholes from the northern end of the site (the last eight entries in Table I) were then compared in the region between anhydrite a and MB138. All the clay seams, breaks, and partings from the logs are identified in Figure 4. Clusters of clay discontinuities and/or argillaceous halite layers are noted in all the logs. Their general locations are not significantly different from those found at the southern end of the site. For this reason, it seems that although D079 has fewer impurities than are found at the southern end of the site, it is far from pure and it would not be unreasonable to include clay discontinuities or argillaceous layers in a model at the clustered regions shown in Figure 4. The thicknesses of the argillaceous layers in this region were taken as a subjective average of that seen in DH227, DH215, D052, and from Figure 4.

Unit 4 in Table I has been mapped in all the drifts at the site. For consistency, these maps were used at locations nearest each of the corehole locations in Table I and the resulting values entered in the table.

C. Locations and Identification of Layers

The locations and identifications of each of the layers for the September '83 Reference Stratigraphy are shown in Figure 5. Averages over the entire site which are listed in Table I have been used for most of the layers.

The layers above clay L were taken from the logs of the ventilation shaft and exploratory shaft. The average height of the layers above mid-height of MB138 was taken from the shaft logs and this same elevation difference was used to construct Figure 5.

The layers below anhydrite c were taken from the logs of ERDA 9. In Table III, the significant layers from the geologic log of ERDA 9 are compared to the position of layers from Table I. We note that the two stratigraphic columns are very similar. This is used to justify the use of the ERDA 9 log to append MB140 and MB141 to the data in Table I. The distance between anhydrite c, MB140 and MB141 are taken for the Reference Stratigraphy to be the same as for ERDA 9. The values are shown in parentheses in Table III.

The thicknesses and locations of the combined layers on the ERDA 9 log denoted as MB136, MB140, and MB141 in Table III were found as follows. Adjacent layer thicknesses were added to obtain the thickness of the idealized layer. (This included three thin polyhalite layers in MB136 and one thin one in MB140 as well as a thin claystone layer in MB141. The properties are similar enough to make this a reasonable approximation). The location of the idealized layer was found by requiring the average height (first moment) to be identical to the actual layers. This averaging was necessary since the several layers in each case were interspersed with halite layers.

Anhydrite b is shown in Figure 5 but should not be included in a structural model since it is too thin to be structurally sound. Its presence as an elastic layer in a model could introduce a local stiffness that is not physically realizable.

The clay layers are designated with letters from A through M and are taken to be of zero thickness. A clay layer C was originally defined in the rough draft of this report but was subsequently removed after discussions with various participants. The remaining layers retained their original designations.

Table III.
Midheights of Significant Layers Taken from the Geologic Log of ERDA 9 as Compared with Table I.

Layer I.D.	Height Above the Datum (m)	
	ERDA 9	Table I
MB136	30.79	30.61
MB137	23.47	---
MB138	9.39	9.26
Anhydrite	5.19	---
Anhydrite a	2.20	2.20
Anhydrite b	---	.03
MB139	-8.29	-8.20
Anhydrite c	-16.76	-16.37
MB140	-28.56	(-28.17)
MB141	-52.82	(-52.43)

Note: MB136 includes 7 layers here, MB140 includes 5, and MB141 includes 4.

D. Comparison with Input from Bechtel and TSC/D'Appolonia

Bechtel, TSC/D'Appolonia, and Sandia each proposed an idealized or reference stratigraphy as outlined in Appendix A. The stratigraphies from Bechtel and TSC/D'Appolonia are compared in Figure 6 with the compromise reference described above. The principal difference is that the reference includes several clay seams not present in the others and is a single stratigraphy whereas Bechtel proposed two references, one for the southern end and another for the northern end. The justification for the single stratigraphy is given in Appendix B and discussed above in connection with layer thicknesses and will not be repeated here. The clay seams were included primarily to signal caution to a designer or stress analyst that trouble is possible if mining occurs in these horizons. These are planes (or at least zones) where slip is possible. With the coefficient of friction of 0.4 specified for these seams, most of them will not actually demonstrate slip in most calculations. Since slip planes can increase the cost of an analysis, even if they are not active, it is generally best to omit them from a model if they are not active. This depends upon their location relative to a drift or other disturbance, the coefficient of friction of the clay seam, and the time for which the analysis is to be run. Auxiliary studies can be made to identify active seams in any particular case.

IV. MECHANICAL PROPERTIES

A. Lithostatic Stress and Density

The idealized stratigraphy of the previous section does not extend up to the surface. It is necessary to apply pressure at the top (and bottom) of a structural model of this stratigraphic interval. The value of pressure to be used here is based on the weight of overburden rock above the site. An average density of 2320 kg/m^3 has been calculated [16] by integration of the mass density measured in the well log on ERDA 9 for the interval from the surface to the room horizon. The depth of anhydrite b is given from the geologic logs of the exploratory and vent shafts as 648.24 m and 652.67 m, respectively. Using an average of 650.45 m and the height of 52.87 m to the top of MB 134 (from Figure 5) we find 597.58 m of overburden at the top of the defined stratigraphy. A value of the elevation adjusted acceleration of gravity of 9.790 m/sec^2 is used then to obtain

$$p = (9.790)(597.58)(2320.)$$

$$= 13.57 \text{ MPa } (1968. \text{ psi})$$

This is to be used as the isotropic lithostatic stress state at the top of the stratigraphic section idealized here.

A constant average density over the interval of depth used in the September '83 Reference Stratigraphy can be used for convenience. The value to be used was found by adding all the layers of halite and argillaceous halite to obtain a thickness of 90.02 m. If 99% of this is pure halite, then over the 107.06 m interval studied, we have 89.12 m of halite (2163. kg/m^3) and 17.94 m of other material for which we assume the density of anhydrite (2960. kg/m^3). This mixture gives a weighted average of

$$\rho = \frac{(89.12)(2163.)+(17.94)(2960.)}{107.06}$$

$$= 2300. \text{ kg/m}^3$$

This gives a lithostatic stress at the clay seam F of 14.83 MPa (2150.psi).

B. Thermal and Mechanical Properties

Only five materials are identified in the stratigraphy and listed here. The properties of these layers are given in this section. They are generally the same properties as were identified in the July '81 Reference Stratigraphy [8] and used elsewhere [7,9,10]. This section is organized as follows. Two tables of properties are presented, one with thermal properties and the second with mechanical properties with terms defined in the text. The source of each quantity is then identified or explained.

B1. Thermal Properties

The thermal properties are listed in Table IV. Note that clay is missing from the table. Since the clay seams are generally less than 0.02m (1. in) thick, they are ignored thermally.

The density is taken to be the same value for all materials as discussed in the previous section.

Values of specific heat are also taken to be the same for all materials. The Debye temperature for salt is near room temperature so that the variation of the specific heat with temperature is small at temperatures of interest here.

TABLE IV. Thermal Properties for the WIPP Materials

Material	Density* ρ (Kg/m^3)	Specific* Heat, C_p (J/kg-K)	Coefficient of Linear Thermal Expansion, α (K^{-1})	Thermal Conductivity Parameters	
				λ_{300} (w/mK)	γ
Halite	2300.	860.	45.0 E-6	5.0	1.14
Argillaceous Salt	2300.	860.	40.0 E-6	4.0	1.14
Anhydrite	2300.	860.	20.0 E-6	4.7	1.15
Polyhalite	2300.	860.	24.0 E-6	1.4	0.35

*These values are taken to be the same for convenience in analysis. Actual values differ somewhat.

The coefficients of linear thermal expansion are measured quantities [17]. Core specimens were used for these tests with samples taken at various depths.

Thermal conductivity for the materials [17,18,19] were fitted to the equation

$$\lambda = \lambda_{300} \, (300/T)^{\gamma}$$

where T is temperature in kelvin. The thermal conductivity expression given here has been compared by Torres [20] to data for salt from West Germany where it was found that the values were within roughly ± 3% from room temperature to 200°C.

B2. Elastic Constants

Suggested values for the elastic constants of halite, anhydrite, and polyhalite [18,19,21] are listed in Table V for 25°C and 100°C. Both anhydrite and polyhalite properties show some change with temperature; however, for reference calculations the values for 25°C should be used. Argillaceous halite is considered to be similar to the "clean" halite units and, therefore, should be assigned the same elastic constants. For the present, the elastic constants for the halite and argillaceous halite units are considered to be independent of temperature, and the values indicated for 25°C should be used.

TABLE V. Elastic Constants

	Halite*	Anhydrite **		Polyhalite**	
	25°C	25°C	100°C	25°C	100°C
Young's Modulus (E)	31.0 GPa	75.1 GPa	51 GPa	55.3 GPa	46.1 GPa
Poisson's Ratio, ν	0.25	0.35	0.26	0.36	0.30
Bulk Modulus (K)	20.7 GPa	83.4 GPa	35.4 GPa	65.8 GPa	38.4 GPa
Shear Modulus (μ)	12.4 GPa	27.8 GPa	20.2 GPa	20.3 GPa	17.7 GPa

*Similar constants for Argillaceous Halite are to be used

**As determined from tests [22,23] at a strain rate of 2.1×10^{-4} sec^{-1}

3. Creep Constitutive Properties

The constitutive models for the materials exhibiting creep behavior are described as follows [21].

The strain rate is characterized by the equation:

$$\dot{\varepsilon}_{ij} = -\frac{\nu}{E}\dot{\sigma}_{kk}\,\delta_{ij} + \frac{1+\nu}{E}\,\dot{\sigma}_{ij} + \dot{\varepsilon}^{c}_{ij} + 3\alpha\,\dot{T}\,\delta_{ij} \qquad (2)$$

where

σ_{ij} are the components of the stress tensor.

ν is the Poisson's ratio.

E is Young's modulus.

T is temperature, degrees kelvin.

α is coefficient of linear thermal expansion.

δ_{ij} is the Kronecker Delta,

and the creep strain rate, $\dot{\varepsilon}^{c}_{ij}$, is given by:

$$\dot{\varepsilon}^{c}_{ij} = \left|\dot{\varepsilon}^{c}_{kl}\right| \frac{\sigma'_{ij}}{|\sigma'_{mn}|} \qquad (3)$$

where σ'_{ij} are the components of the deviatoric stress tensor. Standard summation convention is implied.

For the case in which only secondary creep (steady state) is considered, the magnitude of the creep strain rate can be expressed in terms of the effective creep strain rate, $\dot{\bar{\varepsilon}}$, or the effective stress, $\bar{\sigma}$, as follows [24]:

$$\left|\dot{\varepsilon}^{c}_{ij}\right| = \sqrt{1.5}\;\dot{\bar{\varepsilon}} \qquad (4a)$$

$$\dot{\bar{\varepsilon}} = D\,\bar{\sigma}^{n}\,\exp(-Q/RT) \quad . \qquad (4b)$$

where $\dot{\bar{\varepsilon}}$ is defined as:

$$\dot{\bar{\varepsilon}} = \left(\frac{2}{3}\ \dot{\varepsilon}^{c}_{ij}\ \dot{\varepsilon}^{c}_{ij}\right)^{1/2} \qquad (5)$$

while $\bar{\sigma}$ is

$$\bar{\sigma} = \left(\frac{3}{2}\ \sigma'_{ij}\ \sigma'_{ij}\right)^{1/2} \qquad (6)$$

D, n are constants determined from data analysis.

T is temperature, degrees kelvin.

Q is the effective activation energy, cal/mole.

R is the universal gas constant, 1.987 cal/mole-K.

Values for the parameters are given in Table VI.

Table VI. Constants for Reference Creep Law
(Repository Level, Nominal Elevation 390 m)

Material	Primary Constants			Secondary Constants		
	A	B	$\dot{\varepsilon}^*$ (sec^{-1})	D ($Pa^{-4.9}/sec$)	n	Q (Kcal/mole)
Halite	4.56	127	5.39 E-8	5.79 E-36	4.9	12.0
Argillaceous Halite	4 56	127	5.39 E-8	1.74 E-35	4.9	12.0

In many cases, clay seams can be modeled by a slip line, which allows compressive but no tensile normal stresses. Transverse forces can be transmitted with the frictional coefficient given in Section B5 for clay seam mechanical response.

The creep constants are based on the analysis of data presented in References 24, 25, and 26. The expressions used here are equivalent to those in Reference 24 but have been expressed in terms of effective strain rate.

A factor of 2/3 must be used to convert the steady state shear creep strain rate ($\dot{\gamma}_s$) in a triaxial test to effective creep strain rate $\dot{\bar{\varepsilon}}$ as:

$$\dot{\bar{\varepsilon}} = 2/3 \ \dot{\gamma}_s \tag{7}$$

Reference values for secondary creep strain rates from these formulations are given in Table VII:

Table VII Secondary Creep Effective Strain Rate $\dot{\bar{\varepsilon}}$

Temperature	Effective Stress	
	5 MPa	15 MPa
300°K	7.02 E-12	1.53 E-9
350°K	1.25 E-10	2.71 E-8

If primary creep is to be included in the constitutive model, the primary creep rate is derived [26;(Eqs 27, 28, 29; p 19)] in the following manner.

The effective creep strain rate is the sum of the secondary and primary terms as:

$$\dot{\bar{\varepsilon}} = \dot{\varepsilon}_s + \dot{\varepsilon}_p \tag{8}$$

The secondary term $\dot{\varepsilon}_s$ is defined exactly as before (Eq 4b), and the primary term $\dot{\varepsilon}_p$ is obtained from the solution of the following differential equation:

$$\dot{\varepsilon}_p = (A\text{-}B\ \varepsilon_p)\dot{\varepsilon}_s \text{ for } \dot{\varepsilon}_s \geq \dot{\varepsilon}^* \tag{9a}$$

and

$$\dot{\varepsilon}_p = (A\text{-}B\ \frac{\dot{\varepsilon}^*}{\dot{\varepsilon}_s}\ \varepsilon_p)\dot{\varepsilon}_s \text{ for } \dot{\varepsilon}_s < \dot{\varepsilon}^* \tag{9b}$$

where the initial condition of $\varepsilon_p = 0$ at $t = 0$ is assumed.

The primary creep constants A, B, and $\dot{\varepsilon}^*$ are given in Table VI. Equations (3), (4), and (8) are combined to give:

$$\dot{\varepsilon}^c_{ij} = 1.5 \frac{\sigma'_{ij}}{|\sigma'_{mn}|} \left[D\bar{\sigma}^n \exp(-Q/RT) + \dot{\varepsilon}_p \right] \tag{10}$$

where $\dot{\varepsilon}_p$ is given by Eqs (9).

The argillaceous halite is not considered to be significantly different from the "clean" halite. The secondary creep constants indicated in Table VI for argillaceous halite are derived from preliminary test results [27].

The failure of halite can be described using a failure function ϕ such that when ϕ becomes positive, halite no longer supports any deviatoric stress. This function will be assumed to be given by the following:

$$\phi = \bar{\varepsilon} - 0.023 - f(p) \tag{11}$$

where p is the pressure which is positive in compression, $\bar{\varepsilon}$ is the effecive creep strain found from the integration of Eqn (3) using Eqs (4) or (10) and the expression:

$$f(p) = \begin{cases} 0.132 \text{ for } p \geq 6.0 \text{ E6 Pa} \\ p(a-bp) \text{ otherwise} \end{cases} \tag{12}$$

Here $a = 4.43$ E-8 Pa^{-1}, and $b = 3.7$ E-15 Pa^{-2}.

The relation between pressure and effective strain for $\phi = 0$ is shown in Figure 7.

B4. Anhydrite and Polyhalite Failure Criteria

The mechanical response of both anhydrite and polyhalite can be considered as isotropic and linearly elastic up until failure [22,23]. Failure is described in terms of the fracture stress or ultimate strength of the rock, which is the maximum load it can support in a stress-strain test. Ultimate strengths of both rocks can be assumed to be independent of temperature between 25°C and 100°C, and creep can also be ignored.

Fracture of both rocks can be described equally well by two fracture criteria because insufficient information exists to distinguish between the two (the differences are expected to be small) [22]. The Mohr-Coulomb criterion can be stated in terms of resolved principal stresses where $\sigma_1 \leq \sigma_2 \leq \sigma_3$ as

$$\sigma_3 - \sigma_1 = 2\tau_0 \cos\beta - (\sigma_3+\sigma_1)\sin\beta \quad (13)$$

The Drucker-Prager is the other criterion which can be used and is stated as

$$\sqrt{J_2'} = C - aJ_1 \quad (14)$$

where $\sqrt{J_2'}$ is the second deviatoric stress invariant, and is equal to $\bar{\sigma}/\sqrt{3}$ and J_1 is the first stress invariant or the sum of the three normal stress components. Constants for these equations are given in Table VIII [22,23]. For anhydrite, there is a slight decrease in ultimate strength with decrease in strain rate of approximately 5% for every decade of strain rate change, i.e., a 10% decrease in going from 10^{-4} sec^{-1} to 10^{-6} sec^{-1}. Polyhalite ultimate strengths can be assumed independent of strain rate.

Although there is very little deviation of stress-strain curves from elastic response as the fracture stress is approached, a yield point is detectable in both rocks. The yield point is defined as the onset of dilatancy. Since some designs are based on yield rather than ultimate strength, yield stress design parameters are also listed in Table VIII. The yield point of anhydrite is consistently observed to be 75% of the ultimate strength and is 81% of the ultimate strength for polyhalite.

Table VIII. Failure Parameters* for Anhydrite and Polyhalite

Type of Failure	Anhydrite	Polyhalite
Ultimate		
Mohr-Colomb	τ_0 = 30 MPa	τ_0 = 18.9 MPa
	β = 37°	β = 51°
Drucker-Prager	a = 0.279	a = 0.395
	c = 36 MPa	c = 19.8 MPa
Yield		
Mohr-Coulomb	σ_0 = 27 MPa	σ_0 = 17.2 MPa
	β = 29°	β = 46.5°
Drucker-Prager	a = 0.226	a = 0.361
	c = 33 MPa	c = 19.3 MPa

*Data from triaxial compression tests at strain rates of approximately 2.1×10^{-4} sec^{-1} [22,23].

B5. Clay Seam Mechanical Response

Clay seams in the middle to lower part of the Salado formation at the WIPP site are described as [28]:

1. At most a few centimeters thick
2. Having nonplanar bounding surfaces
3. Having evaporite growths of halite, anhydrite, and polyhalite penetrating into them
4. Having a significant component of quartz and illite.

Thus, the clay seams tend to be simply layers of evaporites which contain higher concentrations of silicates than adjacent evaporites. Clay seams D, I and J in Figure 5 actually correspond to clusters of thin clay partings similar to those seen in Figure 4. Their combined behavior is taken to be that of a clay seam. In view of the "grit" interspersed in the clay minerals and the nonplanar bounding surfaces, a coefficient of static and dynamic friction of 0.4 is recommended for all reference calculations. This simple description of clay with a dry friction model may appear to the uninitiated as an ad hoc assumption. This is not the case however. The bulk clay might conventionally be modeled as a Mohr-Coulomb material. For the special case of a thin layer, the relation between these two models can be shown as follows.

The Mohr-Coulomb material is taken to be an elastic-perfectly plastic material with a yield stress, Y, which varies linearly with pressure, p, as given by

$$Y = \tau_0 + p \tan \phi$$

where p is positive in compression. For a set of experimentally observed yield stresses under specified pressures, the constants α and ϕ may be determined. The general yield condition is then written as

$$(a+cp)^2 = \frac{1}{2}\left[(\sigma_{11}-\sigma_{22})^2 + (\sigma_{22}-\sigma_{33})^2 + (\sigma_{33}-\sigma_{11})^2\right] + 3\left[\sigma_{12}^2 + \sigma_{13}^2 + \sigma_{23}^2\right]$$

A thin clay seam is now considered in a geologic setting where the normal stress components are roughly equal to each other, i.e.,

$$p \cong -\sigma_{11} \cong -\sigma_{22} \cong -\sigma_{33}$$

where the normal stresses are positive in tension. The coordinate system is oriented such that the x_1-direction is normal to the plane of the seam and the x_2-direction is in the direction of motion or incipient motion.

Then σ_{12} is the only non-zero term on the right side of Eqn (11) so that it may be rewritten as

$$\sigma_{12} = \frac{\alpha - \sigma_{11} \tan \phi}{\sqrt{3}}$$

If the cohesive strength is small, then Eqn (12) is the form of a dry friction law:

$$\sigma_{12} = \mu \, |\sigma_{11}|$$

Thus, Eqn (12) applies to a Mohr-Coulomb material under clay seam conditions. In spite of this correspondence between the dry friction surface model and Mohr-Coulomb bulk behavior, it is preferable to consider a clay seam as a dry friction surface. This is due to the asperity or roughness of the seam as well as its waviness. The friction factor μ is then increased to account for the seam geometry as well as the basic bulk properties of the clay.

A complete statement of behavior of the clay seam model then is:

if $\sigma_{12} < \mu|\sigma_{11}|$ then no slip occurs and if $\sigma_{12} = \mu|\sigma_{11}|$ then slip takes place and the shear stress is limited to this value. The effect of clay seams on overall behavior of the drifts in the repository has been studied in some detail [29]. Mechanical modeling [30] and numerical behavior of the model has also been of some concern [31]. These studies have shown that the seams near the drift will be active for $\mu = 0.4$, that this is a reasonable value, and that clay seam separation is unlikely unless the seam is very near the drift. The effect of these clay seams is significant in regard to room closure and is discussed in Reference 29.

V. SUMMARY

The September '83 Reference Stratigraphy has been described as shown in Figure 5. The new stratigraphy consists of one polyhalite layer, three argillaceous halite layers, eight anhydrite layers, 12 clay seams, and halite as the remaining constituent. No mixed polyhalite/anhydrite/halite layers are included. The definition of the new stratigraphy is based on Bechtel, the TSC/D'Appolonia, and Sandia interpretations of a detailed re-examination by a selected group of individuals from these concerns of core from four selected coreholes. The location and thicknesses of the various layers were then adjusted by averaging values taken from the 41 core logs listed in Table I. Logs from the vent shaft, exploratory shaft, and ERDA 9 were used for layers remote from the horizon. The uniformity of the logs, the lack of a statistical significance in bed thicknesses and elevation variation, and the expected small influence on structural behavior resulted in a decision to use the same reference stratigraphy everywhere over the site. Anhydrite b was used as the datum layer, and elevations of other layers are specified with respect to it. It is not to be included in the model because of its small thickness.

Properties of materials are listed in Tables IV through VIII and are similar to previously used properties. A change has been made in the lithostatic pressure to be used at the top of the stratigraphic interval. A change in the average density to be used for the stratigraphic section has also been made.

The reader is cautioned that the September '83 Reference Stratigraphy is intended for structural modeling and does not include many stratigraphic details. The core logs are available and should be consulted if details are important. The reader is also reminded that while the Reference Stratigraphy and Material Properties are the basis for structural calculations and by the project participants, parameteric studies and associated analyses are not meant to be precluded by this document. It is expected that this document will be updated as more data beccme available.

Progress Review Meeting on Stratigraphy and Thermal and Mechanical Properties Near the Working Horizon at the WIPP

July 7, 1983
8:00am - 4:30pm
Coronado Club, Room B4, Kirtland Base East
Albuquerque, NM

A standard abstracted stratigraphy and set of mechanical and thermal properties was first agreed upon by a group of experimentalists, field geologists, and structural analysts in November 1979. This has been a useful concept both for structural/thermal analyses and for design of experiments at the WIPP. The two shafts have been logged at the WIPP site and about a mile of drifts have been excavated. Some new materials tests have also been performed and some old data reanalyzed. The standard stratigraphy and set of material properties should be updated at this time to include the new information. This data base is not complete since all mechanical tests will not be completed for quite some time. However, many important calculations must be started and experimental detail decisions made prior to test completions. The new standard stratigraphy and set of properties is not meant to be a final set but rather an update.

The progress review meeting is not intended to be a showcase for the latest and greatest tools, techniques, and achievements, but rather intended to be a working meeting. The review meeting participants will collectively reach decisions which will allow an updated standard stratigraphy document to be constructed. Some participants are being asked to prepare presentations on work which directly bears on the decisions to be made by the group. Discussions and decisions on each limited topic will follow the presentation on that particular topic.

As you realize, it is difficult for a diverse group of individuals to reach decisions on anything. The success of this meeting then depends upon:

1. *an attitude of cooperation and unity of purpose, not competition and divisiveness.*
2. *conscientious preparation of "homework assignments" by participants who are asked to make presentations.*
3. *a structured program with limited scope of discussion topics.*

It is felt that these are achievable goals considering the participants who are being invited. Lunch will be served at the Coronado Club to the invitees to relieve the intensity of the meeting without rushing the meal in the time allowed.

This workshop should result in an enjoyable, tiring but satisfying day.

PROGRESS REVIEW MEETING AGENDA

Chairman: T. Hunter

8:00 *SNL, Hunter, Introduction and statement of ground rules*

STRATIGRAPHY INTRODUCTION

8:20 *Bechtel - Roberts - Concerns, needs, and uses by Bechtel for the standard stratigraphy definition and other recommendations*

8:30 *SNL, Branstetter - Sensitivity of closure in the South Drift to the initial stress state and concerns, needs, and uses by Sandia for the standard stratigraphy definition*

8:40 *TSC - Sources of data base for definition of stratigraphy*

8:50 *Directed discussion on stratigraphy, necessity for horizontal variations in the standard but no decisions on the details until properties are defined*

PROPERTIES ON ROCK SALT

9:25 *SNL, Krieg - Sensitivity of closure to variations in low stress creep behavior and other secondary creep properties, homogeneity of properties, variations in elastic moduli*

9:40 *SNL, Wawersik - Update on secondary creep description*

9:55 *Discussion on rock salt properties*

10:25 *Break*

10:40 *Decision on a standard set of properties - for rock salt*

PROPERTIES OF CLAY SEAMS

11:10 *SNL, Stone - Sensitivity of closure to clay seam friction coefficient*

11:20 *TSC - Clay seam studies*

11:30 *SNL, Butcher - Update on clay seam mechanical property studies*

11:40 *Discussion on clay seam description and decision on standard properties for seams present*

12:00 *Lunch*

PROPERTIES OF OTHER LAYERS

1:00 *SNL, Stein - Status of tests on constituents in the mixed layers*

1:10 *SNL, Wawersik - Interpretation and consequences of tests on mixed layers*

1:20 *Discussion on anhydrite, polyhalite, and mixed layers and decisions on a standard set of properties*

STRATIGRAPHY DECISION

2:00 *Bechtel - A proposed standard stratigraphy*

2:10 *TSC - A proposed standard stratigraphy*

2:20 *SNL, Krieg - A proposed standard stratigraphy*

2:30 *Discussion on stratigraphy and proposed models*

2:45 *Break*

3:00 *Decision on standard stratigraphy*

3:30 *Break*

ACTION ITEMS

4:00 *SNL, Krieg - Summary of standard stratigraphy and properties*

4:15 *Assignment of action items and conclusions*

4:30 *Closure*

Notes from Progress Review Meeting on
Stratigraphy and Mechanical Properties Near the Working Horizon at the WIPP
July 7, 1983
Albuquerque, New Mexico

The meeting consisted of participants from Sandia, Bechtel and the TSC/D'Appolonia in the WIPP project to establish and update the reference properties to describe the rocks in the underground in the WIPP. The introduction to the meeting by T. O. Hunter consisted of a discussion of the overall purpose of the modeling and calculational effort in its relation to design. Two aspects are important in terms of this activity. One is the establishment of the technical basis for the design, and a development of the associated technology and technology demonstration as regard to WIPP's role as an R&D facility. The project is operating with a structure such that Bechtel will develop the design validation including the conclusions about the validity of the design relative to the original design assumptions. These conclusions and activities will be supported by other project participants who provide data and information supportive to that goal. Sandia will provide modeling studies and laboratory property determinations of materials which support the Bechtel design calculations. The TSC/D'Appolonia will provide interpretations of the sight geology and their impact on the development of reference, stratigraphy and properties.

The design process consists of many elements. These include the design objectives and the design basis in the actual engineering design itself. Within the engineering design are included the calculations which are necessary to form the basis for that design, as well as other empirical techniques and engineering design practices which are used to establish design of an underground facility. Two other key elements include the stratigraphy of the rocks near the working level and the assumptions about rock properties in the different geologic units. Thes two subjects, the stratigraphy and the rock properties are the subject of today's meeting. Other meetings have discussed the basis for the calculations and the basis for the design. Tomorrow's meeting will address measurement techniques and field observations that are used to correlate the design assumptions with the actual data. Finally the process consists of conclusions about the design process itself which will be part of both the design validation report by Bechtel and the conclusions regarding the R&D repository development in rock salt. The format of the meeting consists of presentations on selected subjects and focus discussions about how to develop or establish agreement on the items addressed.

The first series of presentations consisted of establishing the need in basis for development of a stratigraphy in the WIPP. The first presentation was by Dale Roberts of Bechtel.

The basis for reference stratigraphies in Bechtel's use is as a model for calculations. They are concerned about spacial variations in the stratigraphy and how it impacts design calculations. Particularly, Howard Taylor from Bechtel described how they will concentrate on calculations in the storage rooms and then associated calculations in the south drift for the design validation calculations.

Linda Branstetter, Sandia, presented a discussion of the sensitivity of the calculations to various parameters. The parameters included the density and hence the original lithostatic stress and its variation on room closure. She pointed out that it is important to establish the uncertainties in the material data and their influence on rock response. Further it was pointed out that the stratigraphic assumption should be as simple as possible, but should include the relevant mechanisms which are operative.

Dev Shukla, D'Appolonia, pointed out the basic difference between the models and assumptions about stratigraphy. He described that models and stratigraphic assumptions can be based on different views. The operational view in which one looks carefully at intervals near the drift, perhaps plus or minus 50 feet, the view of room closure or longer term room response in which one looks one looks at rock and rock performance at greater depth, perhaps plus or minus 150 feet, and finally when one looks at regional or overlying formation response, it is necessary to have general stratigraphies to depths of about 3000 feet. One conclusion that was made from the discussion by the TSC/D'Appolonia was that everyone agrees that there is good lateral continuity of the beds, the south drift variations are ranged from approximately 27 to 24 feet for the facility horizon. Hence, the uncertainty in material properties appears to be the most important parameter at the present, not the lateral continuity or variability of the beds.

An assessment of the session on introduction to stratigraphy was that we should establish what is important in terms of needs for stratigraphy. It was clear that important primers include bed thicknesses, placing location and properties, and the identification and modeling of mixed layers. Further, it appears to be important to resolve what is a special variation in the stratigraphic assumptions. Also discussed was the importance of applying this stratigraphy to the modeling in determining which primers are really important ones for the intent of the modeling. An additional discussion took place regarding the need for correlation of geophysical techniques to determine in situ rock properties from boreholes within the drift in order to simplify the assumptions about characterizing stratigraphy as well as to allow development of priorities for the testing of laboratory samples.

The second session was devoted to the properties of rock salt. Ray Krieg of Sandia described the series of parameters or assumptions which can be important in terms of the overall modeling. He described the early studies which were done with analytical formulations to decide whether or not the elastic terms were important. It was concluded that these were important in these studies and have since been incorporated in the computer modeling. Second, he described the studies on elastic properties that have been done with the finite element codes, and shows that the lowering of the sheer moduli can result in a significant impact on room closure, and, in fact, may provide a better agreement with the field data. Third, he described the effect of random properties in the studies that were done to try to look at the variation in laboratory properties on the overall impact on room closure. Fourth, he described the effect of low stress or stress cutoff on the

deformation of the rooms. It was concluded that depending on the spacial variation of stress, the existence of a low cutoff stress can be important and affect the room closure. Further, it was discussed that a correlation can be made between the existence of a cutoff stress and the long-term deformation process studies that are being done by David Borns of Sandia, and this correlation should be made. Fifth, he discussed the effect of primary creep and indicated that from Sandia's view, primary creep calculations appear to be expensive, but may be necessary if it is important to model the early time behavior. Finally, he indicated that the need and accuracy of comparing data with calculations is probably better in the long term than in the short term, and discouraged the use of equivalent parameters or factors to try to model the data, but rather emphasized a more fundamental understanding of what parameters are important and how they affect the rock response.

In the same session Wolfgang Wawersik discussed the status of secondary creep modeling in data that we have. He showed new data which indicate that Q values for example, and stress exponents may change from the reference creep law. He indicated that the new data is much higher quality and would tend to change the numbers that have been used in the past. However, from a discussion from a practical point of view, he concluded that the current model is reasonably accurate to represent a good approximation at this time. He indicated, though, that the new samples may show that two types of rocks should be considered. One is basic rock salt, primarily anhydrite, which he concluded from what he had seen in the underground at WIPP, was very similar to the assumptions of the upper level WIPP salt in the original investigations. In addition, though, there may be areas which are truly argillaceous rock salt which could exhibit a higher creep property, perhaps a factor of 2 to 5, and this should be examined further. Finally, he discussed the potential for the uniqueness of secondary creep as a equilibrium state under deformation. It is not clear if, in fact, this is exhibited by the laboratory tests and subsequent microscopic examinations. However, practically speaking, this may not be significant, but could, in fact, alter the assumptions about the reference creep law. He did indicate that there are extremely good results from strategic petroleum reserve calculations about cavern response and fluid volumes which corroborate the data correlations made for WIPP. Barry Butcher pointed out that it is important to establish a threshold about which we are not longer concerned about the impact on the predicted response. Some number like creep response within plus or minus 30% was noted as being insignificant in terms of concern about material properties.

In the same section Mr. Ching Wu from Bechtel, discussed the material concepts which he felt were needed to satisfy design validation. These included: 1) the definition of the materials, 2) the elastic constants, 3) the coefficient of friction of clay seams, 4) the unconfined compressive strength of the rocks, 5) the tensile constants, 6) appropriate failure criteria, and 7) primary creep characteristics. Mr. Li from Bechtel indicated some questions about the use of the primary creep law which may indicate typographical errors in the Sandia reference creep law. Further, he sought clarification on the use of the failure criteria for halite described in the reference creep law.

The next section consisted of discussion of the properties of clay seams. Mike Stone, Sandia, presented a result of defective clay seams on room response, and indicated that previous studies showed that for certain stratigraphies that is not necessary to incorporate all of the clay seams in a particular calculation. However, it appeared that the clay seams have a significant effect on not only room closure, but also on the closure rates, which may be strongly affected. He pointed out that the determination of which clay seams are active should be decided upon by the analysis based on the reference stratigraphy.

Franzoni of TSC/D'Appolonia reviewed the data from clay seam performance obtained in supporting document 12 in the SPDV experiment document. He discussed the Atterberg limits test, the tensile test and the direct shear test, the latter of which indicated that the coefficient of frictions ranged from 0.2 to 0.7 and significant cohesion around 100 psi was observed in the test from the data fitting. Finally, he indicated that tensile strengths of greater than 100 psi
were observed in some of the clay samples taken.

Barry Butcher discussed the prior data in assumptions about clay seam characterization and indicated that a reasonable categorization should be established for what kind of clay seams are actually present, whether they are uniform flat slipping, clay seams which have significant undulations, or in fact consist of mixed layers with intergranular clay which exhibit a similar response.

The discussions of properties of other layers indicated that we should in fact deal with four major rock types. The rock salt, the clay seams, major anhydrite ore, stiff elastic members and finally a mixed unit which is principally argillaceous rock. Carol Stein reviewed the mineralogical investigations which had been performed on drill holes near the WIPP drifts which show that the maximum impurity content for all of the samples throughout the sequence within 50 feet of the drift is about 5% water insoluble impurities, hence the clay content or the anhydrite polyhalite content is limited to just a few percent. It was concluded that more samples need to be taken and a better correlation of the mineralogical analysis with the SPDV data logging should be undertaken. Finally, it was observed that there is no evidence for either mixed polyhalite or mixed anhydrite units which would be significant. Wolfgang Wawersik pointed out that based on his qualitative interpretation he had not observed any mixed layers except perhaps the argillaceous units which would provide any different material response than we had observed in the upper level layers assumed in the original statistical study of creep properties.

The next discussion revolved around the stratigraphy which should be adopted as a reference for the WIPP project. Bechtel, TSC/D'Appolonia and Sandia presented proposed stratigraphies. Bechtel's Howard Taylor indicated that they were concerned about clay seams very near the room including the definition of argillaceous units as perhaps clay partings. The TSC/D'Appolonia Dale Stephenson, indicated that they had adopted three proposed stratigraphies, one about 3,000 ft in extent, one about 300 ft. in extent, and one about 100 ft. in extent.

They based their referencing on the anhydrite units which are very near the rooms and indicated that those, in fact, are continuous in most cases, although reasonably thin and can be used as a basis for the stratigraphy. Ray Krieg, Sandia, compared the original 1979 stratigraphy which was adopted in 9/82 and discussed the possible variations which should be considered.

At that point a general discussion followed on the importance of various layers to the reference stratigraphy. It was pointed out that all of the argillaceous layers may contain clay seams and hence should be considered as possible slip planes or points of extreme weakness. Consequently, further consideration should be given to examining those cores. Some discussion took place on the halite-halite contacts observed above the rooms. It was concluded that these were local details and not sufficiently wide-spread to be considered in the reference stratigraphy. Further discussion on materials properties was that at this point we can concentrate on intergranular impurities, principally those associated with the argillaceous material to establish a difference in creep response for the various materials.

At that point Ray Krieg presented the underlying assumptions for a reference stratigraphy, and indicated that he would take the three proposed stratigraphies, match them up and provide a common reference stratigraphy for all participants to review.

A summary of the modifications to the reference stratigraphy and material properties is as follows:

> In terms of the material description it was concluded that the primary creep assumptions will remain unchanged at this point. The secondary creep assumptions will remain unchanged, the elastic moduli based on unloading will remain the base case, but the analyst will be allowed to determine whether or not these moduli or moduli based on the secant modulus will be used in conjunction with the secondary creep models. It was suggested that a model which seems reasonable would be to leave the bulk modulus constant and to lower the shear modulus by a factor of four. It was further concluded that the failure models for rock salt will remain the original formulation of the reference creep law based on pressure and total strain.

The polyhalitic halite will be modeled as rock salt and no distinction will be made for polyhalite in conjunction with halite as a different material.

The anhydrite will be modeled with the same elastic properties and the same failure criteria if used as was developed by Sandia and available literature on the subject, and this will be presented in the new reference creep law. The argillaceous halite will require separate action but should be considered as a different material. Two aspects must be considered: 1) whether or not each argillaceous layer should be considered as a slip plane, and 2) whether or not the argillaceous material is sufficiently different mineralogically to introduce different creep properties. These will be evaluated by the creep testing matrix and mineralogical studies being conducted by Sandia.
Finally a list of action items was developed of items which should be done to support the development of a reference stratigraphy. These are outlined in the following list.

ACTION ITEMS

July 7, 1983

1. Compare and correlate mineralogical analyses results (especially argillaceous halite) with stratigraphic section - C. Stein.

2. Evaluate overburden density to surface from drill hole or geophysical (gravity and uphole velocity) data, perhaps comparing structure contour of anhydrite B with surface topography - A. Lappin.

3. Evaluate geophysical techniques for correlating stratigraphic/physical properties information in drill holes from drifts. - TSC/D'Appolonia.

4. Develop further tests to investigate clay seam properties in drill holes considering drilling techniques, drying out, etc. - TSC/D'Appolonia.

5. Develop a referring or characterizing method for clay seams. B. Butcher, C. Stein.

6. Obtain samples of argillaceous rocks from drifts for creep tests (per original test matrix). - C. Christensen.

7. Obtain samples from MB 139 and other anhydrites for quasistatic tests. - C. Christensen.

8. Reinterpret a north/south drill hole combination for comparison of logging data and mineralogical analysis. - Sandia/TSC/D'Appolonia/-Bechtel.

9. Compare proposed reference stratigraphies and develop a new reference for project review. - R. Krieg.

10. Compile and publish a document with reference constitutive models, stratigraphy, and common data base. - R. Krieg and T. Hunter.

APPENDIX B.

Statistical Proof of the Non-Significance of Spacial Variations

The anhydrite layers in Table I have been characterized by their thicknesses and elevations above anhydrite b. We note a considerable variation in the values of these parameters in any given column. The rows are arranged such that the most southerly core is at the top of the table and the most northerly at the bottom. Looking over the columns, we see a consistent variation from top to bottom in the absolute elevation of anhydrite b but little regularity in other parameters with the possible exception of the thickness of anhydrite b. Variations in the anhydrite layers listed then appear to be due to ripples or short range, rather than to long range variations. A consequence of this would be that a local measurement would not be as indicative of a mean local region thickness or height as an average value from Table I would be. We need not rely on intuition for this decision since we can statistically examine the quantities in the table.

Each column was considered individually. If X is the north-south location of the core as given in the second column of Table I with south considered to be negative, and if Y is thickness or elevation above anhydrite b, as given in one of the columns, then we make the usual statistical assumptions. We assume that a linear north-south variation does exist and the X locations of the core holes are known. The Y values are assumed to be random variables normally distributed around the assumed linear north-south variation.

If (X_i, Y_i) for i = 1, n are the values from the table, then average values $\overline{X}$ and $\overline{Y}$ are computed to be

$$\overline{X} = \sum_{i=1}^{n} X_i$$

$$\overline{Y} = \sum_{i=1}^{n} Y_i$$

A least squares fit to the data gives the curve:

$$Y = a + bX \tag{B1}$$

where a and b are found using the relations:

$$b = \frac{\Sigma(X_i - \overline{X})(Y_i - \overline{Y})}{\Sigma(X_i - \overline{X})^2} \tag{B2}$$

$$a = \overline{Y} - b\,\overline{X} \tag{B3}$$

where the summations are taken to be over the limits from 1 to n.

The values of a and b are listed in Table B-1. The variance of Y and X is denoted as $S^2_{Y,X}$ and is given as

$$S^2_{Y,X} = \frac{1}{n-2}\left[\Sigma(Y_i-\bar{Y})^2 - b\,\Sigma(X_i-\bar{X})(Y_i-\bar{Y})\right] \tag{B4}$$

This is in turn used to find the variance on the regression coefficients a and b. These variances are given by

$$S^2_b = \frac{S^2_{Y,X}}{(X_i-\bar{X})^2} \tag{B5}$$

$$S^2_a = S^2_{Y,X}\left[\frac{1}{n} + \frac{\bar{X}^2}{\Sigma(X_i-\bar{X})^2}\right] \tag{B6}$$

Another informative and useful measure is obtained by considering the fraction of the total variation in Y that is accounted for by the association between X and Y. The ratio of the sum of squares associated with the regression to the total sum of squares for Y is called the coefficient of determination and is given by

$$r^2 = \frac{\Sigma(a+bX_i-\bar{Y})^2}{\Sigma(Y_i-\bar{Y})^2} \tag{B7}$$

The variances and the coefficient of determination are all listed in Table B.

The variances and coefficient of determination are all informative, but the bottom line is simply an answer to the question of whether the north-south changes in variables in Table I are statistically significant. For this, we go to the t-distribution and consider confidence limits.

We want to know whether or not there is a linear association between X and Y, for if there is not, then there is nothing to be gained by using the X's as they will contribute nothing to the analysis of the Y's. For this, we compute

$$t = \frac{b}{S_b} \tag{B8}$$

This is compared to values for the t-distribution for (n-2) points listed in statistical tables for given confidence intervals. Values for computed and tabular values at 95% confidence interval are listed in Table B-1. The tabular values are greater than computed values for all but the thickness of anhydrite b.

The conclusion is that with a confidence of 95%, it can be said that there is no statistically significant north-south variation in any of the parameters except the thickness of anhydrite b. We further note that the most statistically significant value we can use for these variables is an average over the entire site.

Table B-1. Statistical Parameters Associated with a Spatial Variation Over the WIPP Site

Notes:
1. Parameters a and b are determined as in Eqs (B2) and (B3)
2. The number of samples is denoted as n
3. $S^2_{Y,X}$ is computed in Eqn (B4)
4. S^2_a is computed in Eqn (B6)
5. S^2_b is computed in Eqn (B5)
6. r^2 is computed in Eqn (B7)
7. t_{comp} is computed in Eqn (B8)
8. t_{95} is a standard tabulated 95% confidence value

ABSTRACT

The U.S. Department of Energy (DOE) plans to dispose of transuranic wastes at the Waste Isolation Pilot Plant (WIPP), a geologic repository located at a depth of about 655 meters. The WIPP underground facility is located in the bedded salt of the Salado Formation. Access to the facility is provided through vertical shafts, which will be sealed after decommissioning to limit the release of hazardous waste from the repository and to limit flow into the facility.

Because limited data are available to characterize the properties of dynamically compacted crushed salt, Sandia National Laboratories authorized RE/SPEC to perform additional tests on specimens of dynamically compacted crushed salt. These included shear consolidation creep, permeability, and constant strain-rate triaxial compression tests. A limited number of samples obtained from the large compacted mass produced by Hansen and Ahrens (1996) were available for use in the testing program. Thus, additional tests were performed on samples that were prepared on a smaller scale device in the RE/SPEC laboratory using a dynamic-compaction procedure based on the full-scale construction technique.

The laboratory results were expected to (1) illuminate the phenomenology of crushed-salt deformation behavior and (2) add test results to a small preexisting database for purposes of estimating parameters in a crushed-salt constitutive model. The candidate constitutive model for dynamically compacted crushed salt was refined in parallel with this laboratory testing.

1.0 INTRODUCTION

1.1 Background

The U.S. Department of Energy (DOE) plans to dispose of transuranic wastes at the Waste Isolation Pilot Plant (WIPP) located in southeastern New Mexico. The WIPP is designed to be a full-scale geologic repository, and its underground facility is located in the bedded salt of the Salado Formation at a depth of about 655 meters below ground surface. Access to the facility is provided through vertical shafts. Because these shafts comprise direct communication between lithologic units and connect the underground facility to the surface, they will be sealed to limit the release of hazardous waste from the repository and to limit flow into the facility.

One of the primary seal components in the Salado Formation is dynamically compacted crushed salt. Crushed salt has been selected because of its chemical compatibility with the host salt rock. In addition, crushed salt is an attractive sealing material because its permeability is expected to decrease as the surrounding host salt rock creeps into the shaft and reduces the volume of sealing material (crushed salt). The initial fractional density of the crushed salt at placement will be 0.9 (Sandia National Laboratories, 1996), where fractional density is defined as the ratio of the current bulk density to the density of intact salt (i.e., 2.16 g/cc (Callahan et al., 1998)). Hansen and Ahrens (1998) demonstrated that initial fractional densities of 0.9 could be achieved in a full-scale construction technology demonstration. Their study produced large blocks from which laboratory-scale specimens were subcored for use in laboratory programs.

Because limited data are available to characterize the properties of dynamically compacted crushed salt; the Sandia National Laboratories (SNL) Repository Isolation Systems Department authorized RE/SPEC to perform additional tests on specimens of dynamically compacted crushed salt. The types of tests to be performed included shear consolidation creep, permeability, and constant strain-rate triaxial compression. A limited number of samples obtained from the large compacted mass produced by Hansen and Ahrens were available for use in the testing program. Thus, additional tests were performed on samples that were prepared on a smaller scale device in the RE/SPEC laboratory using a dynamic-compaction procedure based on the full-scale construction technique.

The purpose of the laboratory work was twofold. The laboratory results were expected to (1) illuminate the phenomenology of crushed-salt deformation behavior and (2) add test results to a small preexisting database for purposes of estimating parameters in a crushed-salt constitutive model. The candidate constitutive model for dynamically compacted crushed salt (Callahan et al., 1998b) was refined in parallel with this laboratory testing and the current model refinements have been published (Callahan et al., 1998a). The work was conducted under RE/SPEC's QA Program

as specified in the document, "Quality Assurance Project Plan: Rock Mechanics Analysis Support for Sandia National Laboratories, AG-4911 (RSI Job 325), RSI QAPP-09.

1.2 Organization

In addition to this introduction, this report is organized into five additional chapters and two appendices. Chapter 2.0 provides a description of the specimens used for the testing and the equipment and procedures used to fabricate the laboratory-scale specimens. Chapter 3.0 describes the test equipment and procedures that were used in the study and is followed by Chapter 4.0, which summarizes the results of the testing. Concluding remarks are in Chapter 5.0 followed by a list of cited references in Chapter 6.0. The two appendices contain technical memoranda that outline specific work conducted on crushed salt.

2.0 SPECIMENS

There were two sources of dynamically compacted crushed-salt specimens. The first was the large-scale, dynamically compacted crushed salt recovered from the dynamic-compaction demonstration study (Hansen and Ahrens, 1998) that produced a compacted mass greater than 40 m^3. The second source of specimens was provided by the laboratory-scale, dynamic-compaction device designed and built at RE/SPEC.

The specimens derived from the large-scale dynamically compacted mass provided by SNL (Hansen and Ahrens, 1998) were prepared by dry-coring them from the large blocks and then finishing the ends to produce cylindrical specimens suitable for testing. Finished specimens had a diameter of 100 millimeters and lengths up to 200 millimeters. Some specimens had lengths less than 200 millimeters because of dimensional limitations imposed by the irregular geometry of the large blocks. Hansen and Ahrens also produced a small amount of dynamically compacted material from initial intermediate technology demonstration trials. A few specimens from the intermediate-scale trials were used for early permeability work by Brodsky (Appendix B).

Some of the dynamically compacted crushed-salt specimens used for this laboratory program were fabricated in a laboratory-scale compaction device. This device approximated the compaction technique envisioned for the shaft sealing design. The laboratory-scale compaction device is shown in Figure 2-1. The system uses a 30-pound cylindrical hammer that can be dropped from a height of 1.52 meters (5 feet) through a rail guide that directs the position where the hammer strikes the crushed salt that is contained in a cylindrical mold. The hammer diameter is 50.8 millimeters (2 inches) which equals the radius of the mold. The hammer guide was constructed such that it could be rotated to strike along any desired radius of the specimen. This feature was included in the design to mimic the compaction technique used in the large-scale compaction device operated by SNL. The mold was fabricated from two standard Proctor split compaction molds. The assembled mold is capable of producing a cylindrical sample with a diameter of 101.6 millimeters (4 inches) that can be machined into a specimen with a nominal length of 200 millimeters.

Brodsky (1994) has characterized the disaggregated crushed salt that was used as the raw material for making the laboratory-scale specimens. The crushed salt was subjected to a sieve analysis, and all particles larger than 9.5 millimeters were crushed to pass a 9.5-millimeter sieve and then added back into the mixture. The particle size limit of 9.5 millimeters was selected to ensure the largest particle was less than a tenth of the specimen diameter, which was about 100 millimeters. The sieve analysis of the material satisfying the 9.5-millimeter limit indicated a particle size of approximately 1.8 millimeters at the 50th percentile.

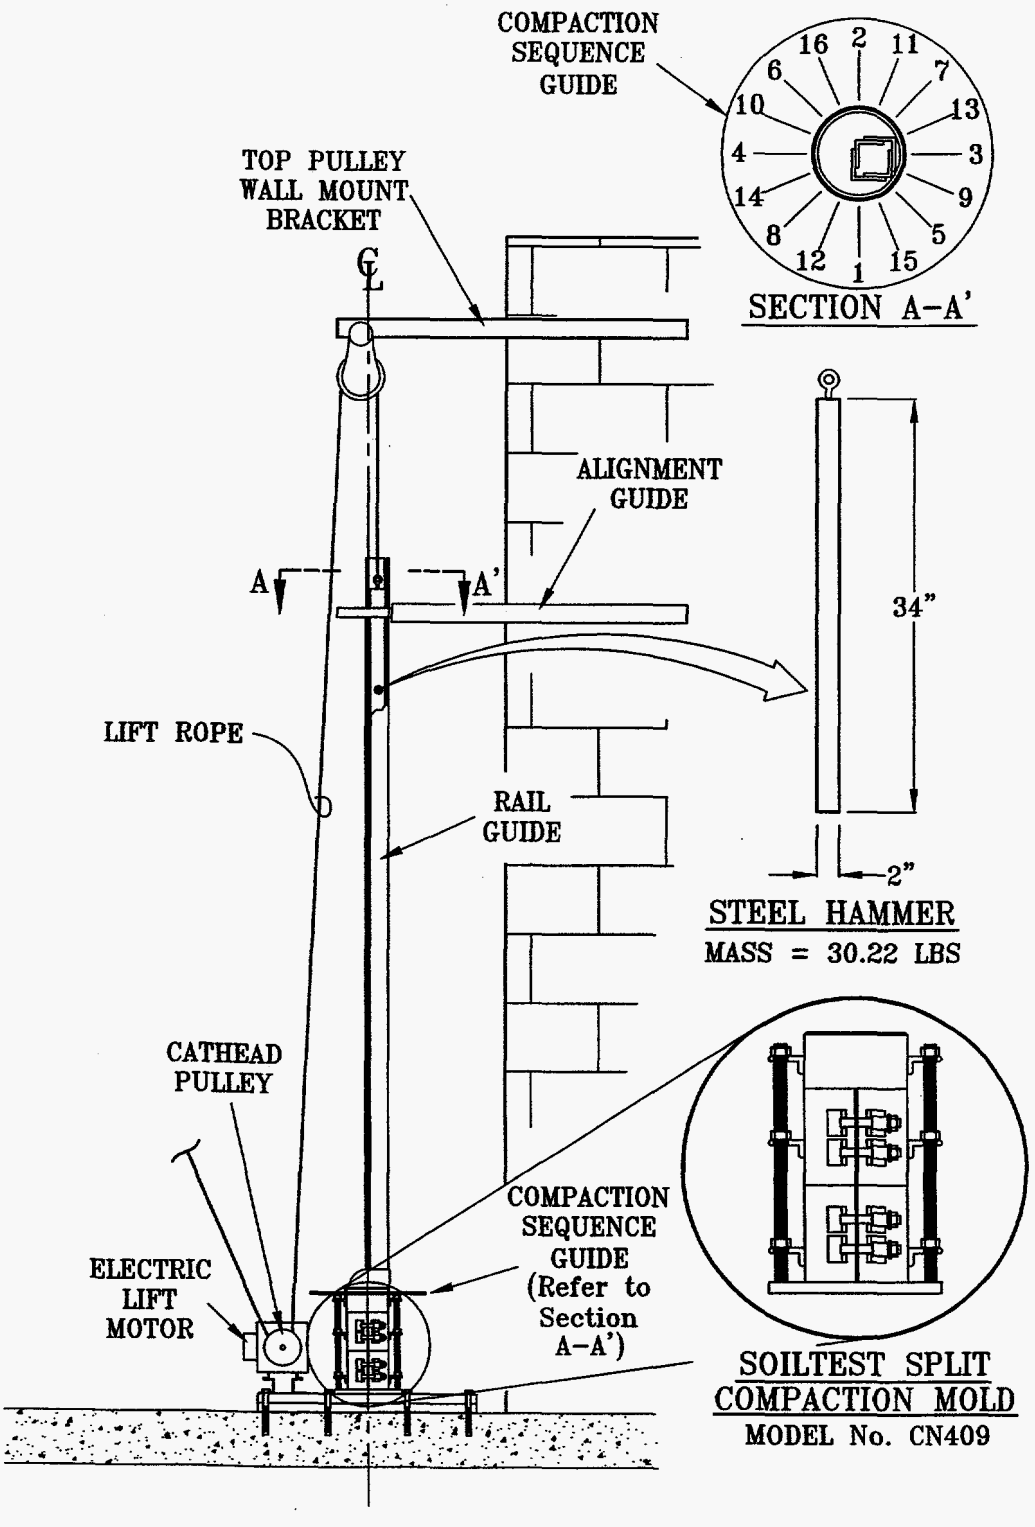

Figure 2-1. Laboratory-scale dynamic-compaction device.

During shakedown testing of the compaction device, the question arose regarding how much friction loss was imparted to the hammer by the rail guide. A simple, comparative method was used to assess the frictional effect by first dropping the hammer from varying heights onto a lead ball target *without* the rail guide in place (free fall) and then repeating the drops *with* the rail guide in place (guided fall). The results of that testing are presented in Figure 2-2, which plots the final deformed thickness of the lead ball versus the drop height. There is one curve for the free-fall tests and one curve for the guided-fall tests. The deformed thickness of the lead balls were compared to determine what the equivalent free-fall drop height was for a given guided-fall drop height. That comparison gave an equivalent free-fall height for each guided-fall height, and the relationship is shown in Figure 2-3. For a guided-fall drop height of 1.52 meters (5 feet), the equivalent free-fall drop height was approximately 1.34 meters (4.4 feet). The equivalent free-fall drop height is the value that was used to calculate the three times, modified-Proctor energy level that was imparted to the specimen during the compaction process.

The specimens fabricated with the laboratory-scale device were identified as RS/DCCS/n, where n took on values of 1, 2, 3, etc. to designate individual specimens. After machining the end of the compacted cylindrical sample, the specimens had final nominal dimensions of 100-millimeter diameter and 200-millimeter length. The starting material was wetted with a WIPP brine that had previously been manufactured at RE/SPEC using distilled water and the same crushed salt used to fabricate the specimens, so the specimen moisture content was nominally 1.6 percent by weight. The initial dry fractional density of the specimens was about 0.9 (assuming intact salt has a density of 2.16 g/cc).

The moisture content of the laboratory-scale specimens was determined using standard laboratory procedures, as described below. Samples of the disaggregated crushed salt were placed in metal containers of known mass. Each sample and container was weighed using a balance having a resolution of 0.01 gram and placed in an oven regulated to a temperature of 110°C. Periodically, the samples and containers were removed from the oven and weighed to monitor the loss of water during drying. When the mass of each sample/container changed by less than 0.01 gram over a 24-hour period, it was assumed that all of the moisture in the sample had been removed. The mass of water contained in the specimen was calculated as the difference between the initial and final masses of the sample/container. Using the data from the drying procedure, values were calculated for moisture content of the samples and density of the test specimens using the following expressions:

$$w = 100\frac{M_w}{M_{ds}} \tag{2-1}$$

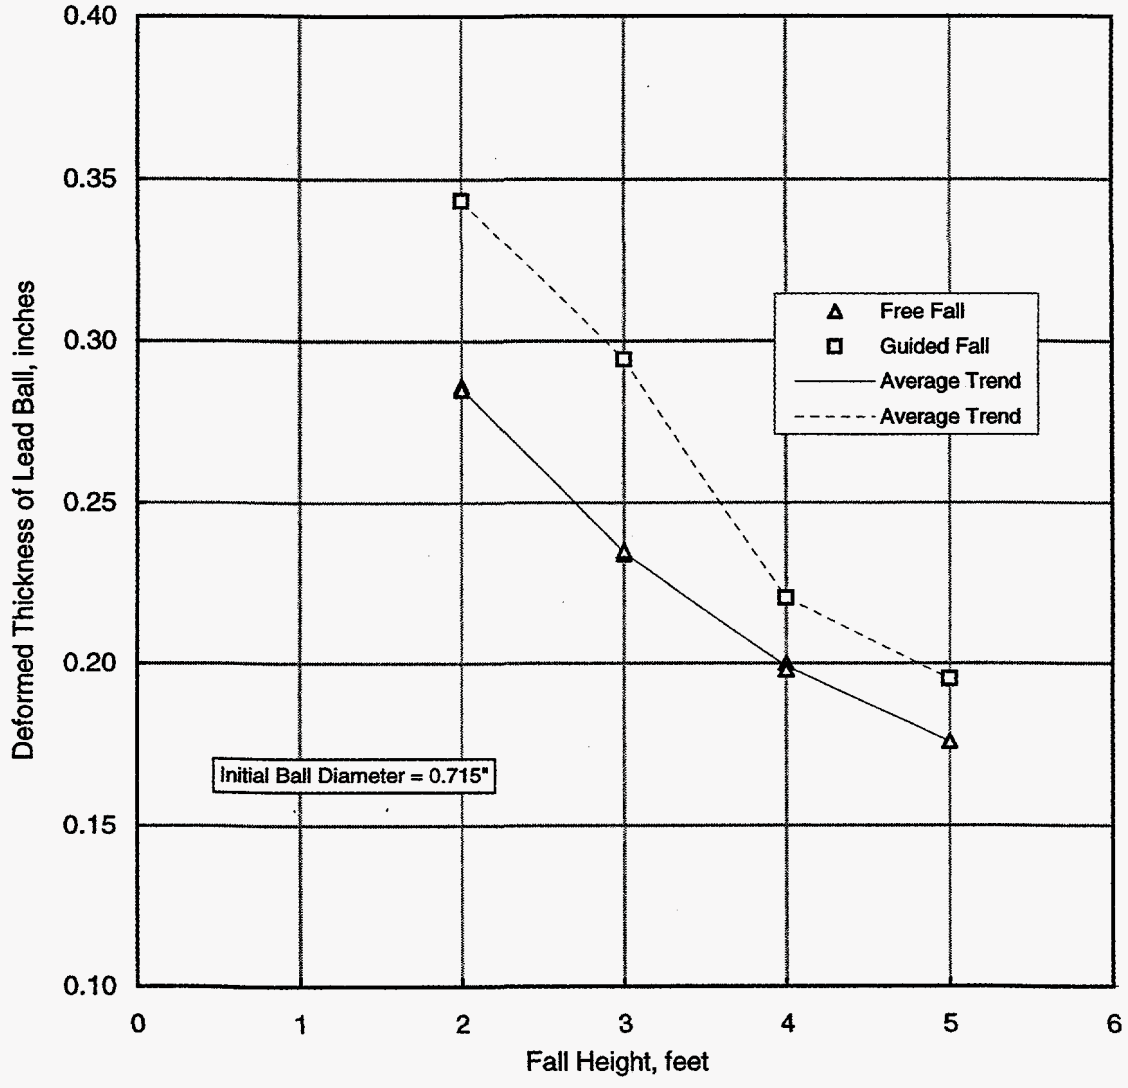

Figure 2-2. Lead ball deformation as a function of drop height.

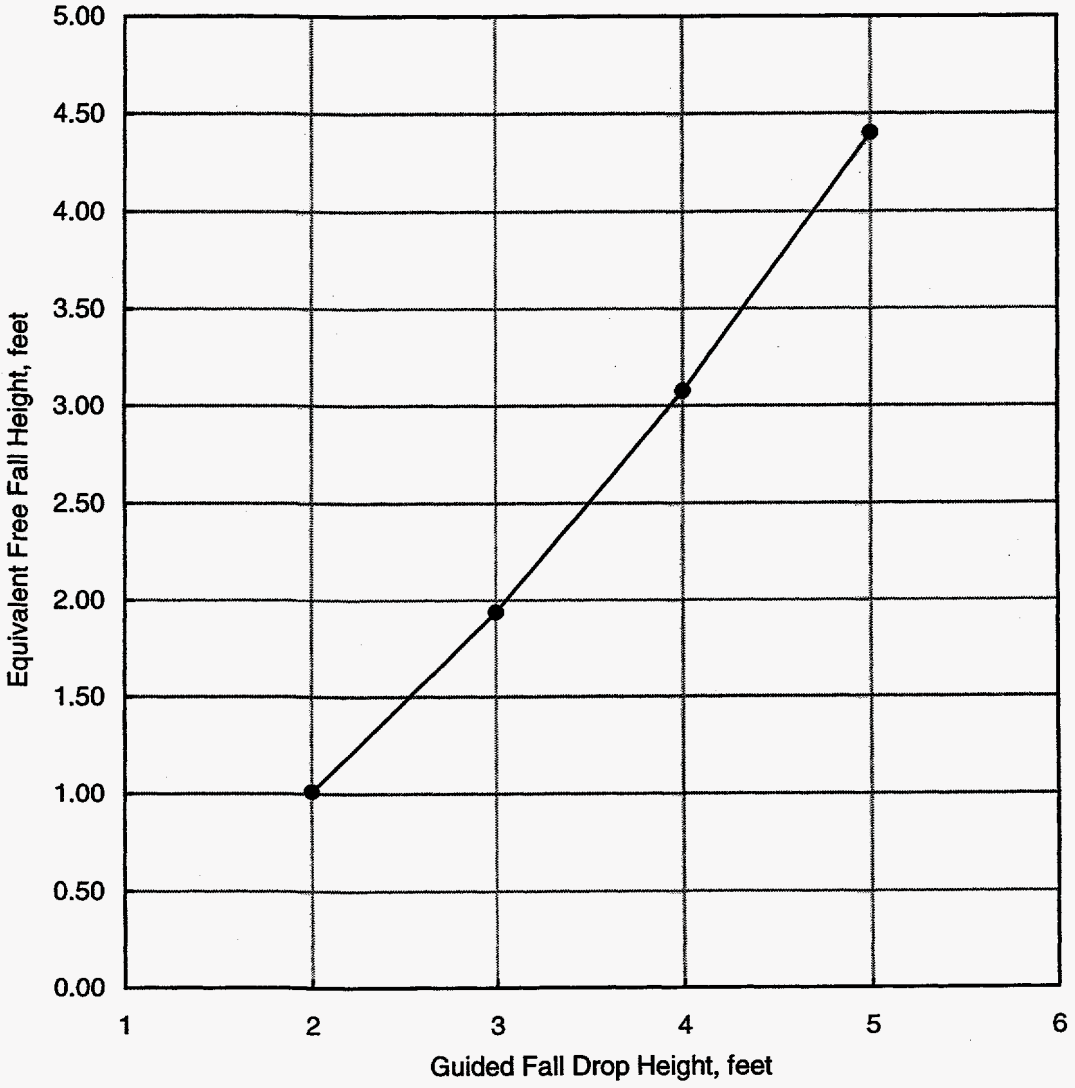

Figure 2-3. Equivalent free-fall drop height as a function of guided-fall drop height.

$$\rho = \frac{M_{ws}}{V_s\left(1+\frac{w}{100}\right)} \tag{2-2}$$

where:

w = percent moisture content
ρ = dry density
M_{ds} = mass of the dry sample
M_{ws} = mass of the wet sample
M_w = mass of water contained in the sample
V_s = volume of specimen.

Volume was determined for finished specimens having regular solid geometries (e.g., solid cylinders) using direct measurements of the specimen dimensions (i.e., length and diameter).

A summary of the moisture contents and densities of the laboratory-scale specimens fabricated at RE/SPEC and used in this study is presented in Table 2-1. The first column is the specimen identification label, and the second column indicates the type of testing applied to that specimen. The third column gives the moisture content for each specimen, and the fourth column lists the dry fractional density for each specimen before it was tested. These dry fractional densities were calculated assuming the density of intact salt is 2.16 g/cc.

A summary of the moisture contents and densities of the large-scale specimens made available by the Hansen and Ahrens experiment and used in this study is presented in Table 2-2. This table is similar to the previous table presented for laboratory-scale specimens produced by RE/SPEC. The fractional densities were calculated assuming the density of intact salt is 2.16 g/cc.

Table 2-1. Laboratory-Scale, Dynamically Compacted Crushed-Salt Specimen

Specimen Identification	Test Type	Moisture Content (%)	Initial Dry Fractional Density
RS/DCCS/1	Shear Consolidation	1.66	0.904
RS/DCCS/3	Shear Consolidation	1.63	0.905
RS/DCCS/4	Shear Consolidation	1.59	0.904
RS/DCCS/5	Shear Consolidation	1.55	0.898

DCCS/3/2/2-1	Gas Permeability	1.27	0.899

(a) These specimens were initially tested using a gas permeant (Appendix B).

3.0 TEST EQUIPMENT AND PROCEDURES

The laboratory program encompassed three different types of experiments: shear consolidation creep, constant strain-rate triaxial compression, and permeability. Petrographic studies of test specimens are contained in this chapter, following test descriptions. The equipment and procedures are discussed in the separate sections.

3.1 Shear Consolidation

The shear consolidation tests were effectively standard creep tests. The specimens were initially loaded hydrostatically to the level of specified confining pressure (radial stress). Following the hydrostatic loading, the axial stress was increased by 4 MPa while the confining pressure was held constant. Each of the tests was the same in this regard, in that each was subjected to a 4 MPa axial stress difference. Only the specified level of the confining pressure varied among tests. Following the application of the axial stress difference, the axial stress difference was held constant at 4 MPa while data were acquired during the creep consolidation phase. At the termination of the test, an unload/reload cycle was performed by reducing the applied axial force to drop the stress difference to near zero and then reapplying the axial force to reload the specimen to a stress difference of 4 MPa before totally unloading the specimen. The ascending loading data from the reloading portion of the cycle were used for estimating elastic constants. The following sections present additional details on the equipment and procedures used for the shear consolidation testing.

3.1.1 Load Frame

Figure 3-1 presents a cross section of a typical consolidation frame with prominent components labeled for reference. The frames used single-ended, triaxial pressure vessels. A linear actuator (hydraulic cylinder) bolted to the base of the load frame advanced the loading piston, which in turn, applied axial compressive force to the specimen. Confining pressure was applied to the jacketed specimens by pressurizing the sealed vessel chamber with silicone oil. A dilatometer system maintained constant confining pressure and provided the volumetric measurement. The testing machines could apply compressive axial loads up to 1.5 MN and confining pressures up to 70 MPa. The heating system, including seals on the pressure vessel, could maintain specimen temperatures up to 200°C, although all the current testing was performed at 25°C. A control panel located near the load frames housed accumulators, hydraulic pumps, pressure intensifiers, transducer signal conditioners, temperature controllers, and confining pressure controllers for two adjacent test frames.

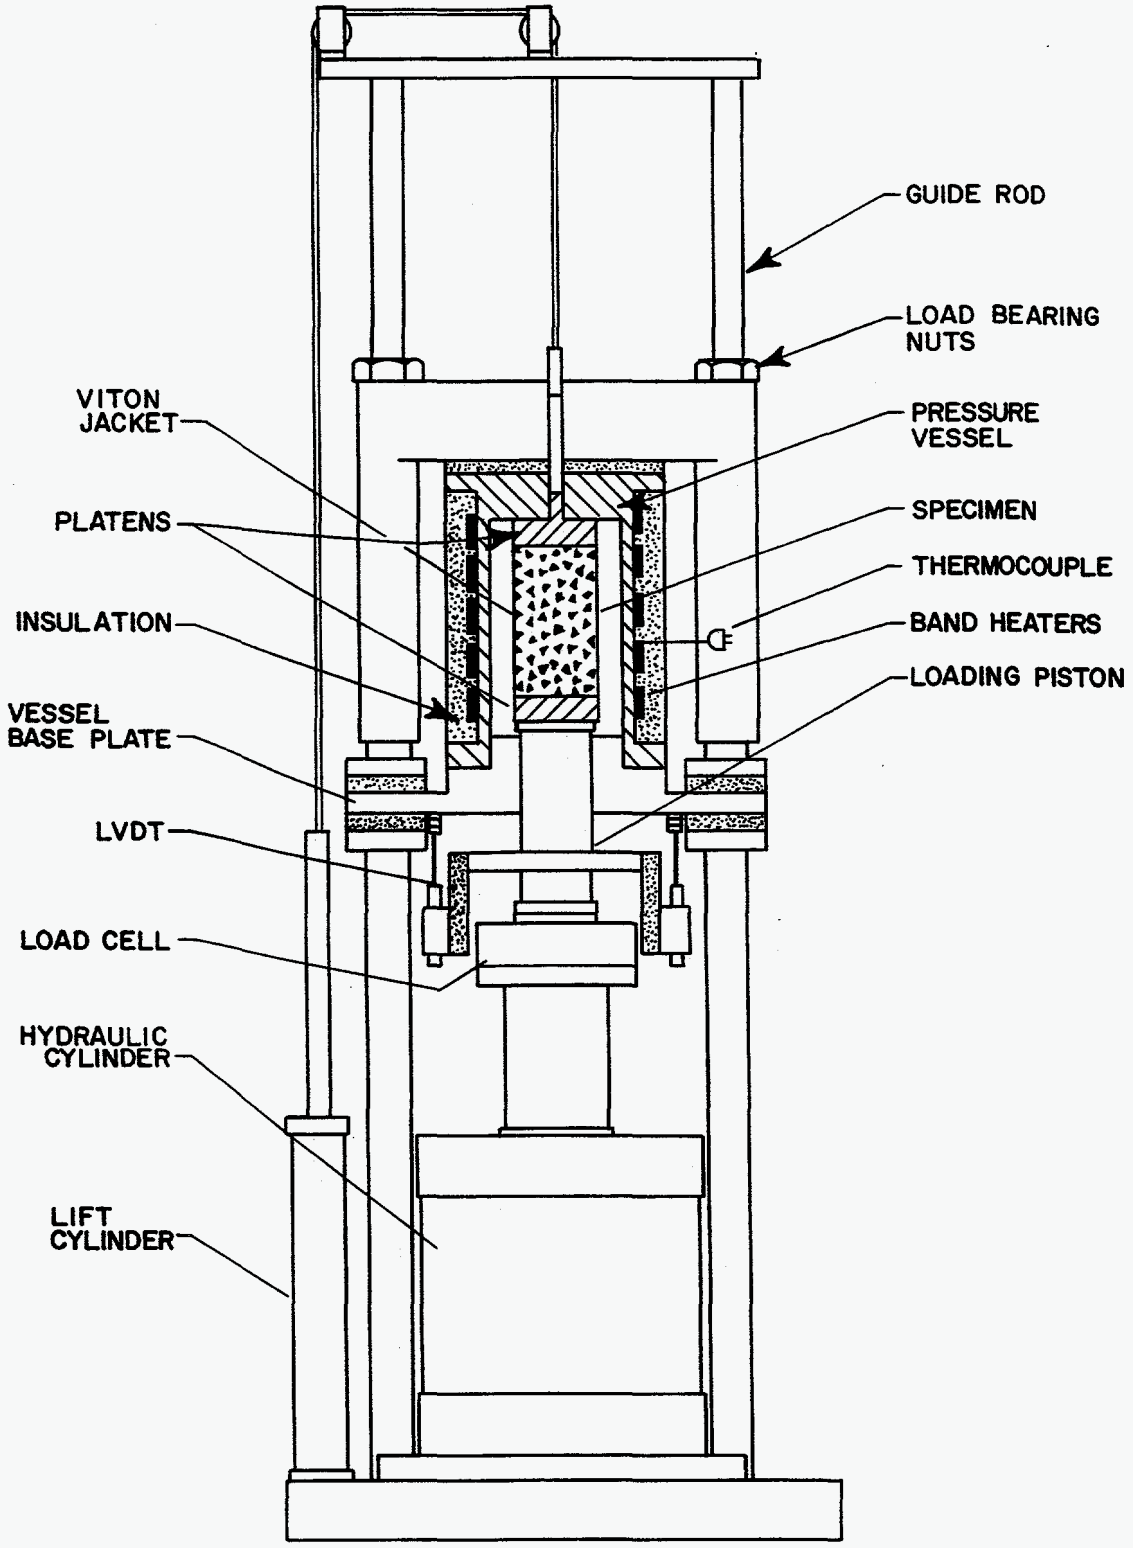

Figure 3-1. Schematic of static triaxial test system.

3.1.2 Instrumentation

Axial force was measured by a load cell located in the load train outside the pressure vessel, while confining pressure was measured by a pressure transducer located in the line between the intensifier and the pressure vessel. Temperature was measured by a thermocouple embedded in the wall of the pressure vessel. The relationship between the actual specimen temperature and the thermocouple measurement has been determined by calibration at several temperatures spanning the operating range. Two linear variable differential transformers (LVDTs) mounted outside the pressure vessel monitored displacement of the loading piston relative to the bottom of the pressure vessel. Volumetric deformation was measured using a dilatometer. With this technique, volumetric deformation was determined at fixed pressure by first measuring the volume of oil that the dilatometer supplied to the pressure vessel, and then compensating for the axial deformation measured by the LVDTs. A stroke transducer was mounted on the dilatometer shaft to provide a signal proportional to the volume of oil, either supplied to or extracted from the pressure vessel.

The transducers used to collect force, pressure, deformation, and temperature data were calibrated under documented RE/SPEC procedures using standards traceable to the National Institute of Standards and Technology (NIST). Each transducer was calibrated in its normal operating position on the test system so that the signal conditioners, filters, and analog-to-digital converters were included within the end-to-end calibration. Calibration constants were determined for each transducer from a linear, least-squares regression of indicated reading versus standard input. Readings were collected at 20 standard inputs equally spaced over the range of the transducer. These constants were verified immediately before testing began by comparing the predicted response of the transducer using these constants, with the standard input applied in ten equally spaced steps over the calibrated range. Acceptance criteria developed for the verification process were based on the following accuracy criteria: 1 percent of reading for force and pressure transducers, 2 percent of reading for deformation transducers, and ±1°C for thermocouples. The accuracy specifications included both linearity and repeatability.

3.1.3 Control

Test system variables were controlled by a personal computer running data acquisition and control software programmed for loading and maintaining creep tests. Temperature was maintained by a software routine that regulated power to the band heaters on the vessel based on a feedback signal provided by a thermocouple in the pressure vessel wall. Confining pressure was controlled by inputting the pressure transducer signal to another routine that maintained the confining pressure within a 20 kPa deadband around the desired pressure. Through the use of digital I/O signals, the pressure control software instructed the dilatometer to advance or retreat,

depending upon whether the lower or upper edge of the deadband had been reached. Axial load was adjusted by a similar software routine to maintain a constant axial stress on the specimen. The program determined the current cross-sectional area of the specimen from the outputs of the deformation transducers and then adjusted the load to maintain constant stress. The deadband on load under this control was 0.4 kN. A standby diesel generator provided electrical power to the test systems during periods of commercial electrical power outages.

3.2 Constant Strain Rate

Three constant strain-rate tests were performed on the laboratory-scale, dynamically compacted crushed salt. All three tests were performed at the same confining pressure (1 MPa), but three different axial strain rates were imposed (0.5×10^{-7}, 1.0×10^{-7}, and 2.0×10^{-7} s^{-1}). The following sections present additional information on the equipment and procedure used to perform the constant strain-rate testing.

3.2.1 Load Frame

A computerized, servohydraulic test frame manufactured by MTS Systems was used to perform the constant strain-rate tests. The test frame is equipped with two reaction posts that provide a total axial force capacity of 0.5 MN. A custom pressure vessel designed by RE/SPEC was mounted in the test frame to provide triaxial compression capability.

The load frame configuration is shown in Figure 3-2 where prominent components have been labeled for reference. The pressure vessel is designed for confining pressure of up to 70 MPa and is fitted with resistance heaters and insulation blankets allowing operation at temperatures of 200°C. However, for this work, the confining pressure was limited to 1 MPa and the tests were all performed at a temperature of 20°C.

3.2.2 Instrumentation

The test system instrumentation was typical of most triaxial compression experiments. The load cell attached to the test frame crosshead recorded total axial force and confining pressure was measured by a pressure transducer located in the line leading from a hydraulic intensifier to the vessel. For specimen deformation measurements, the specimen was encased in a protective jacket and instrumented with deformation transducers, as shown in Figure 3-3. The extensometers shown in Figure 3-3 directly recorded the axial and radial deformations of the specimen over their respective gage lengths. The axial extensometer was an MTS Model 632.90C unit with deformation sensors in both arms. The sensor outputs are combined and scaled into a single analog output voltage, which gets measured by an analog-to-digital converter

(ADC). Simultaneous ADC measurements are made of the output signal provided by the radial deformation extensometer. The radial deformation extensometer is a strain-gaged ring (i.e., lateral disk gage) rigidly connected to two vertical mounting posts that contact the specimen at opposite ends of a diameter located at specimen midheight.

All data were logged with respect to time by using the clock provided by the Digital Equipment Corporation (DEC) 11/73 microprocessor which was the platform running the data acquisition and control software program. The software was written in MTS MultiUser BASIC which is the programming language provided with the system by MTS Systems. The acquired data were archived onto the computer disk and then transferred over a local area network to make them available for postprocessing using standard spreadsheets; e.g., EXCEL 97.

The original specimen dimensions were those measured on the bench before the specimen was encased in its protective jacket. The current specimen dimensions were determined from the deformation measurements made during the test. The change in diameter was measured directly by the lateral disk gage (LDG) mounted across a diameter at the midheight of the specimen. The change in specimen length was calculated by assuming the axial strain measured over the axial extensometer gage length represented the average strain in the specimen. The area of the loading ram was always larger than the area of the specimen.

3.2.3 Control

There were two segments of the load path used to perform a constant strain-rate test. The first segment imposed a hydrostatic load path up to the level of the desired confining pressure, which, for these tests, was 1 MPa. This segment was performed in load control with the servohydraulic control system advancing the axial force and the confining pressure to effect a hydrostatic pressurization rate of 0.02 MPa/second. At this slow pressurization rate, the extensometers were not subjected to thermal drift that could be caused by adiabatic heating of the confining fluid (Mellegard et al., 1993). At the end of the hydrostatic pressurization ramp, the stresses were held constant and the consolidation rates were monitored. If the axial strain rate during hydrostatic consolidation was larger than the axial strain rate specified for the next segment of loading, the load path was held at the hydrostatic state until the consolidation rate fell below the specified axial strain rate. The reason for this delay follows from the constraints imposed by the test machine loading system. If the consolidation rate were higher than the axial strain rate specified for the constant strain-rate segment, the control system would sense a feedback signal that is too high and would attempt to reduce the axial strain rate by removing axial load. Since a test is initiated at a hydrostatic state, the removal of axial load would cause the axial stress to fall below the hydrostatic stress state and a state of triaxial extension would be imposed. The test system

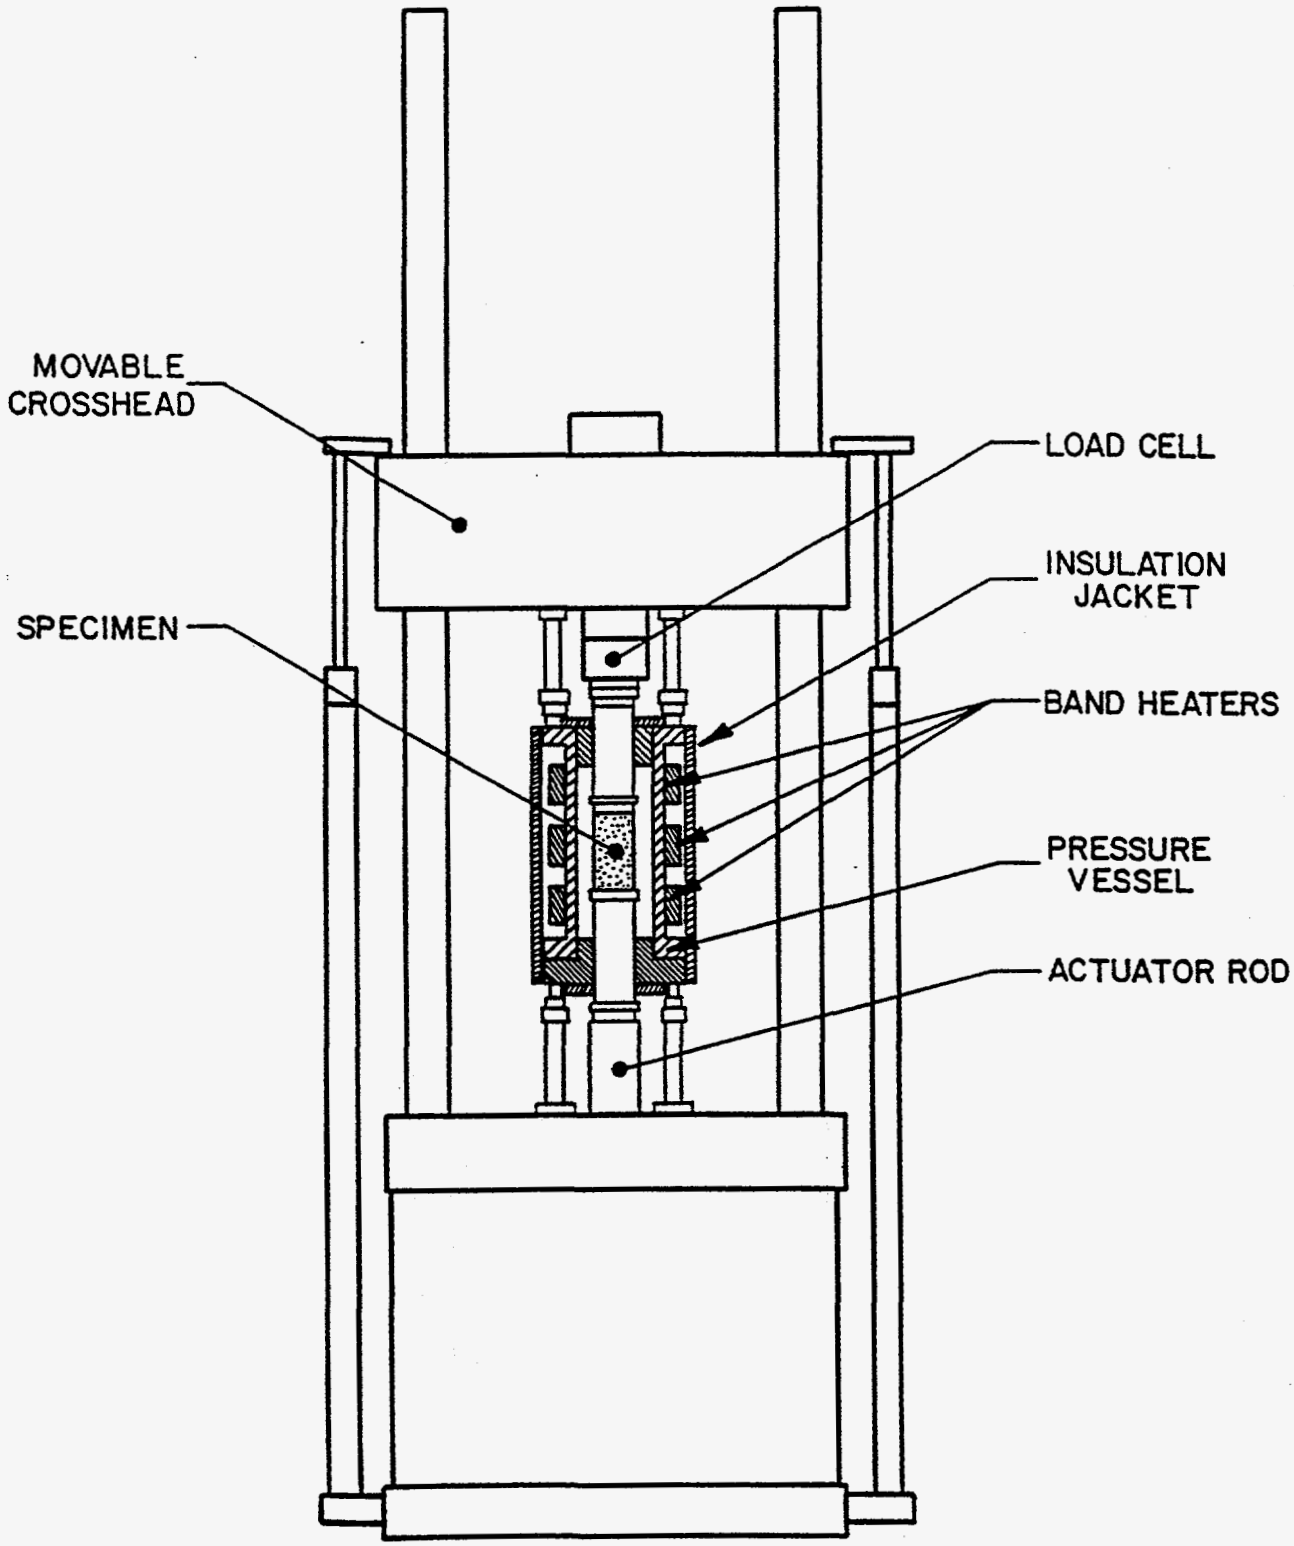

Figure 3-2. Schematic of dynamic triaxial test system.

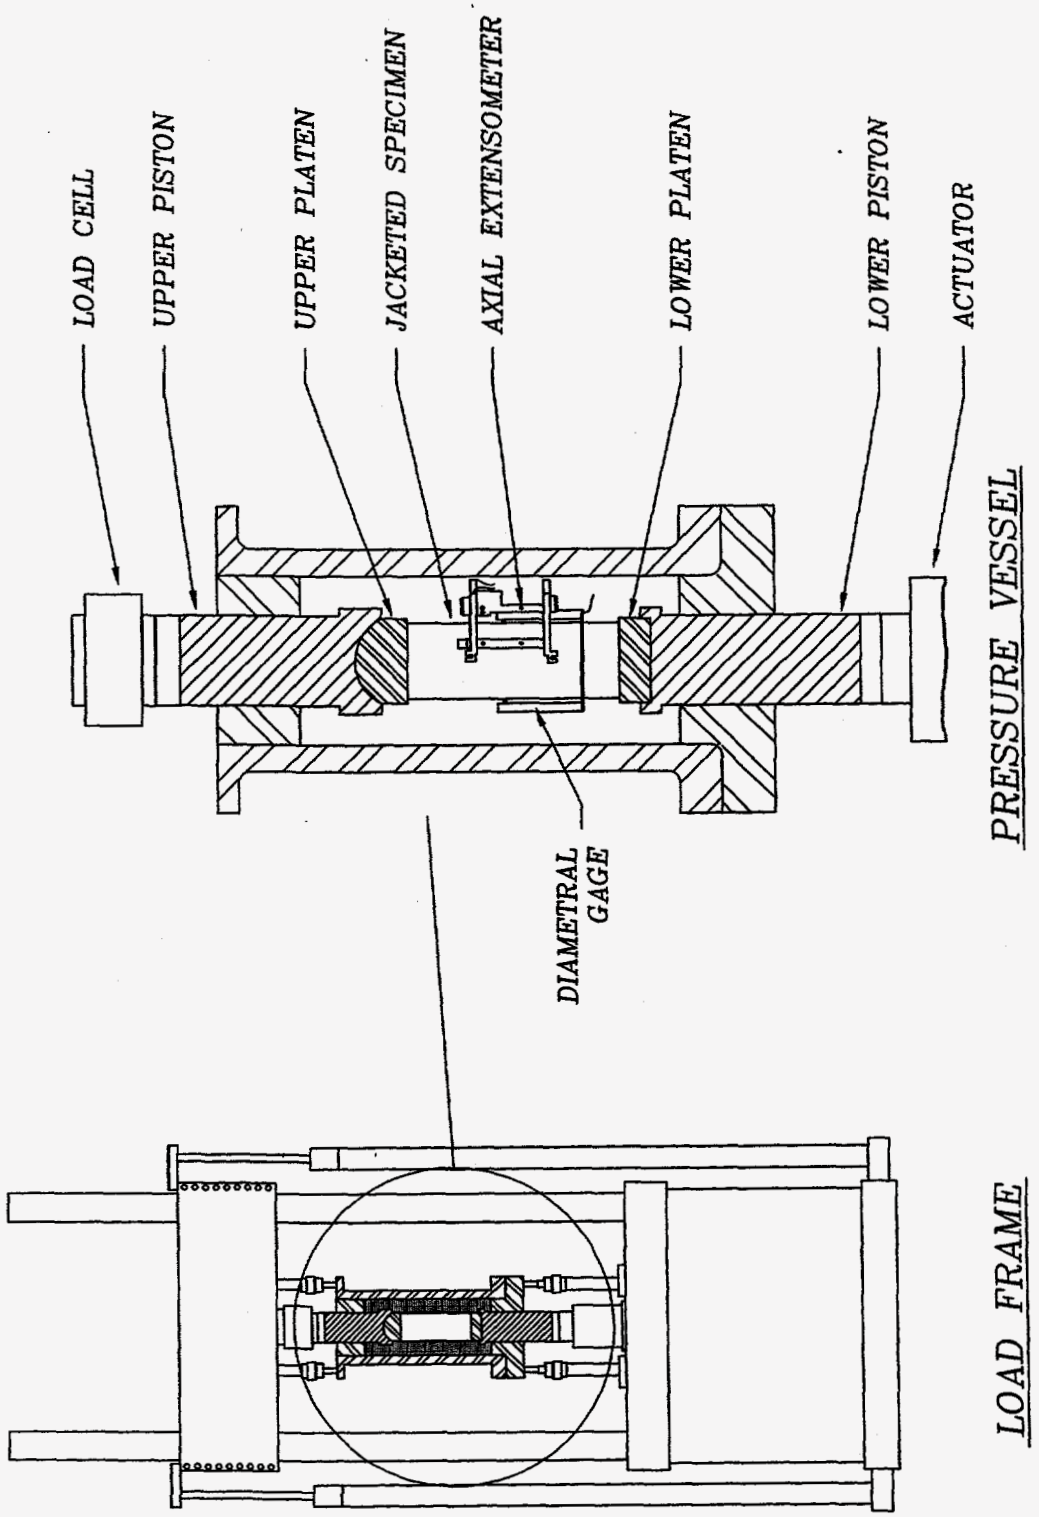

Figure 3-3. Constant strain-rate test setup.

used here will not support triaxial extension because the vessel is a single-ended apparatus. Thus, if the system attempted to impose triaxial extension, the axial loading column would simply decouple and all of the axial load would be removed, effectively terminating the test immediately.

After waiting for the consolidation rates to decrease to an appropriate level, the constant strain-rate segment of the test started. Upon entering the constant strain-rate segment, the mode of axial force control was switched from load to axial strain; i.e., the feedback signal for controlling application of axial load was switched from the load cell to the axial extensometer mounted on the specimen. The command signal provided by the computer was ramped linearly to cause the axial extensometer to deform at the specified constant axial strain rate while the confining pressure was held constant. The axial load increased as required, depending upon the specimen response. The loading was terminated when the deformation transducers reached their maximum operating range.

3.3 Permeability

Specimens identified for permeability testing were placed inside protective flexible Viton sleeves or jackets which were secured to two metal platens positioned at either end of the specimen, as shown in Figure 3-4. The jacket served to protect the specimen from the hydraulic fluid (silicone oil) used to apply radial stress during permeability measurements. Each platen was equipped with a 3.2-millimeter-diameter vent drilled along the central axis of the platen to provide access to porous felt metal disks placed in the specimen/platen interfaces. These disks were used to ensure one-dimensional flow parallel to the central axis of the specimen by inducing uniform permeant pressure across the specimen ends. The specimen assembly shown in Figure 3-4 was placed inside the pressure vessel of the testing frame depicted schematically in Figure 3-1, which is the same test system that was used for the shear consolidation tests.

For those specimens tested with a brine permeant, the specimen exit was connected to the buret measurement system shown in Figure 3-5. Brine permeant was supplied to the specimen inlet by a pressurized accumulator. The charge pressure to the accumulator was controlled manually with a valve located on a nitrogen gas bottle and measured by a pressure transducer located in the hydraulic line at the inlet to the specimen. A hydrostatic stress of 1 MPa was applied to the external surfaces of the specimen by pressurizing the annulus between the specimen and the pressure vessel wall. The valve located at the specimen inlet was then opened to permit the flow of brine through the test specimen. The flow rate at the specimen exit and brine pressure at the specimen inlet were then recorded by reading the buret level and the pressure transducer, respectively. The pressure at the inlet was limited to 0.34 MPa (about one-third the confining pressure) to ensure that the flow paths were through the specimen and not

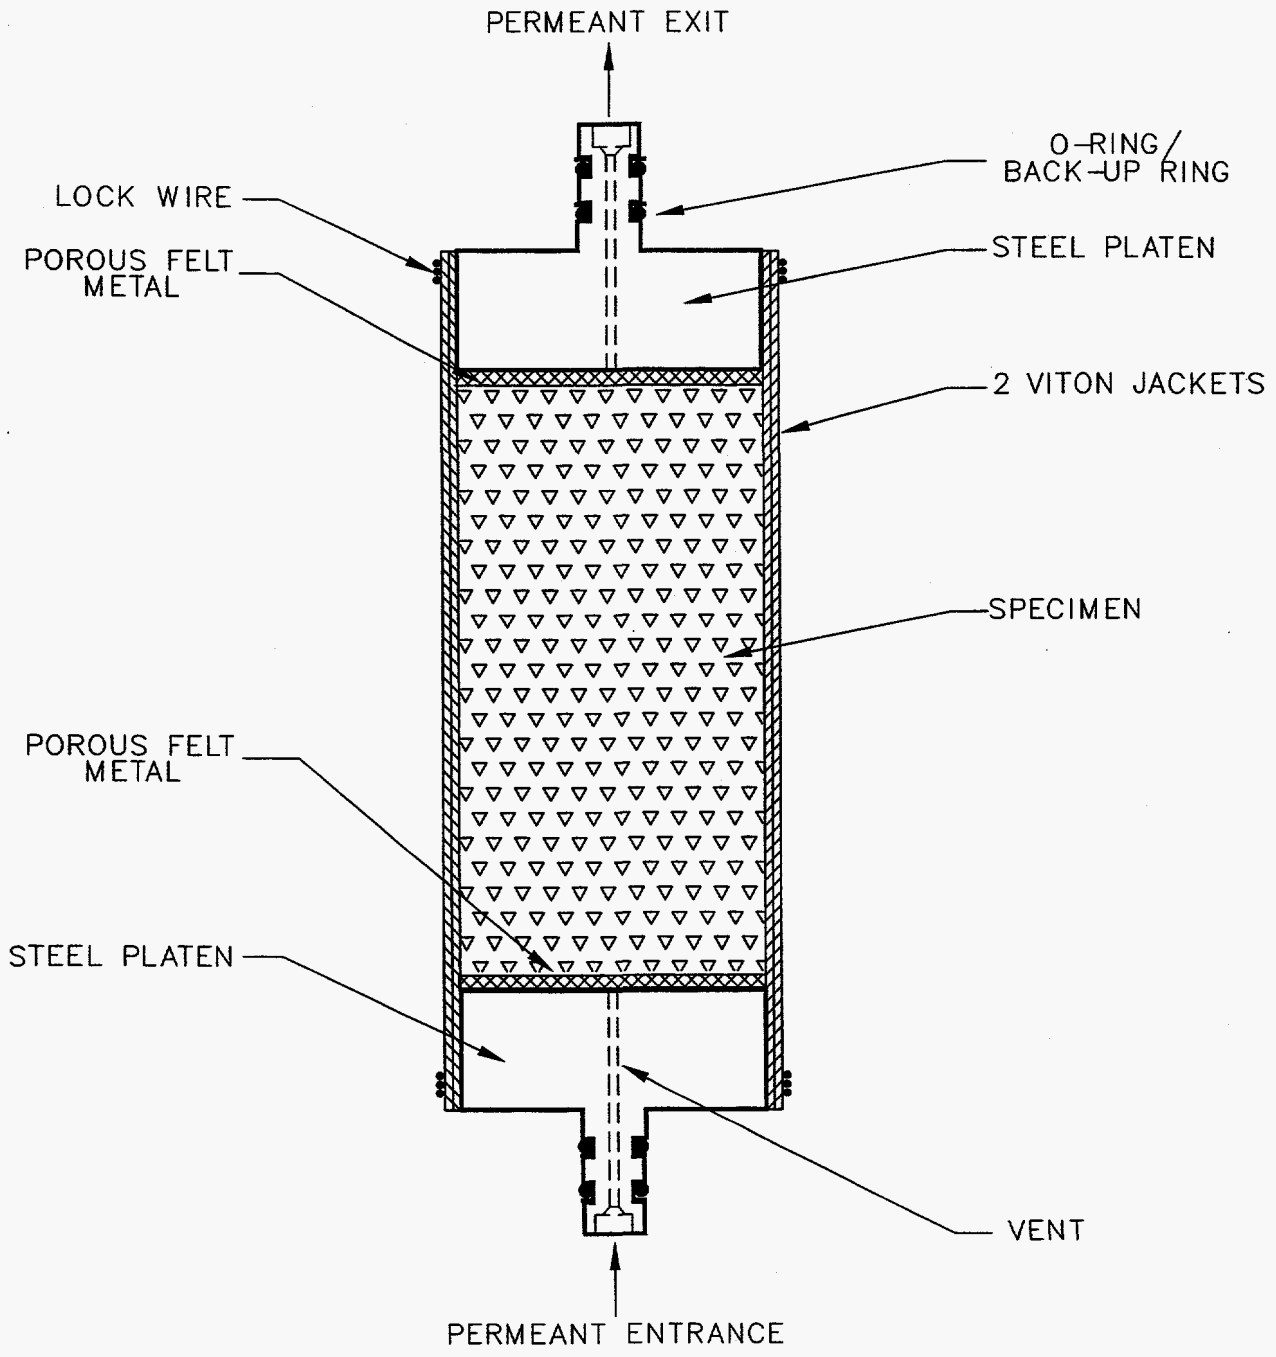

Figure 3-4. Jacketed specimen test assembly.

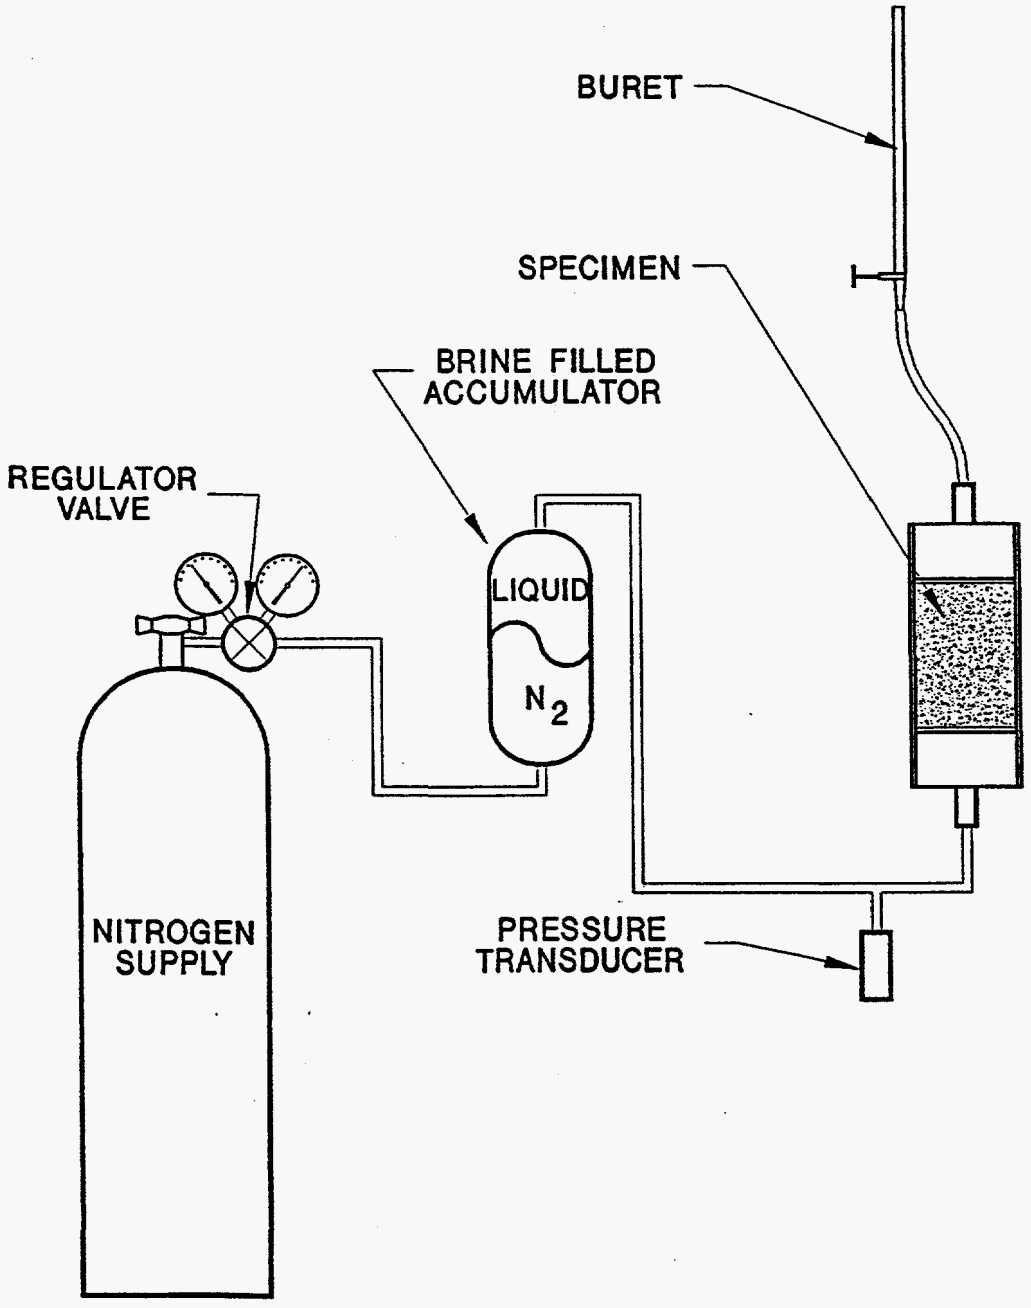

Figure 3-5. Brine permeability test setup.

along the jacket-specimen interface. In some cases where the flow rate was very high, the buret was periodically emptied during the test, and the amount emptied was recorded to calculate the accumulated flow quantity. In extremely high flow tests, the buret was removed entirely and replaced with a balance. The accumulated mass flow rate was then converted to a volume flow rate using the known density of brine (1.208g/cc [Brodsky, 1994]).

For those specimens tested with a gas permeant, the specimen assembly was connected to a rotameter flow meter system, as shown in Figure 3-6. Nitrogen gas was supplied to the flow meter by a pressurized bottle. The charge pressure to the flow meter was manually controlled with a valve located on the gas bottle, and measured by a pressure transducer located in the hydraulic line at the inlet to the flow meter. The flow meter consists of two components: an interchangeable flow tube and a tube holder. The design of the flow meter permits the removal of a tube with a specified maximum flow capacity and the replacement of the tube with another having either a larger or smaller flow capacity so that different flow rates can be accommodated with the same apparatus. The flow meter was hydraulically connected to the specimen using 3/16-inch i.d. stainless steel tubing. A second pressure transducer located in the hydraulic line near the inlet to the specimen provided the measurement for the specimen inlet gas pressure. Gas exiting the specimen was vented to atmosphere. Similar to the brine permeant tests, a hydrostatic stress of 1 MPa was applied to the external surface of the specimen. Then, the valve located on the pressurized nitrogen gas bottle was opened to permit the flow of nitrogen through the flow meter system and test specimen. The pressure at the inlet to the flow meter was adjusted to a value of 0.345 MPa (50 psi), which was the flow meter calibration pressure. The flow rate and gas pressure at the specimen inlet were then recorded by reading the flow meter and pressure transducer outputs, respectively.

Two of the specimens from the large-scale, dynamic-compaction blocks were subjected to a combination of hydrostatic compaction and hydrostatic creep consolidation loading. This loading caused the specimen fractional densities to increase from their initial value of about 0.9. As the specimens were deformed, nitrogen gas permeability measurements were conducted at incrementally higher levels of fractional density. The test system used for these tests was the same as the one described for the constant strain-rate tests, although a particular loading path was applied to the specimens. The loading history for a typical hydrostatic consolidation test can be summarized as follows:

1. A jacketed specimen was placed inside the pressure vessel of the testing machine and hydrostatically loaded to a stress of 1 MPa. A nitrogen gas permeability measurement was performed at this point.

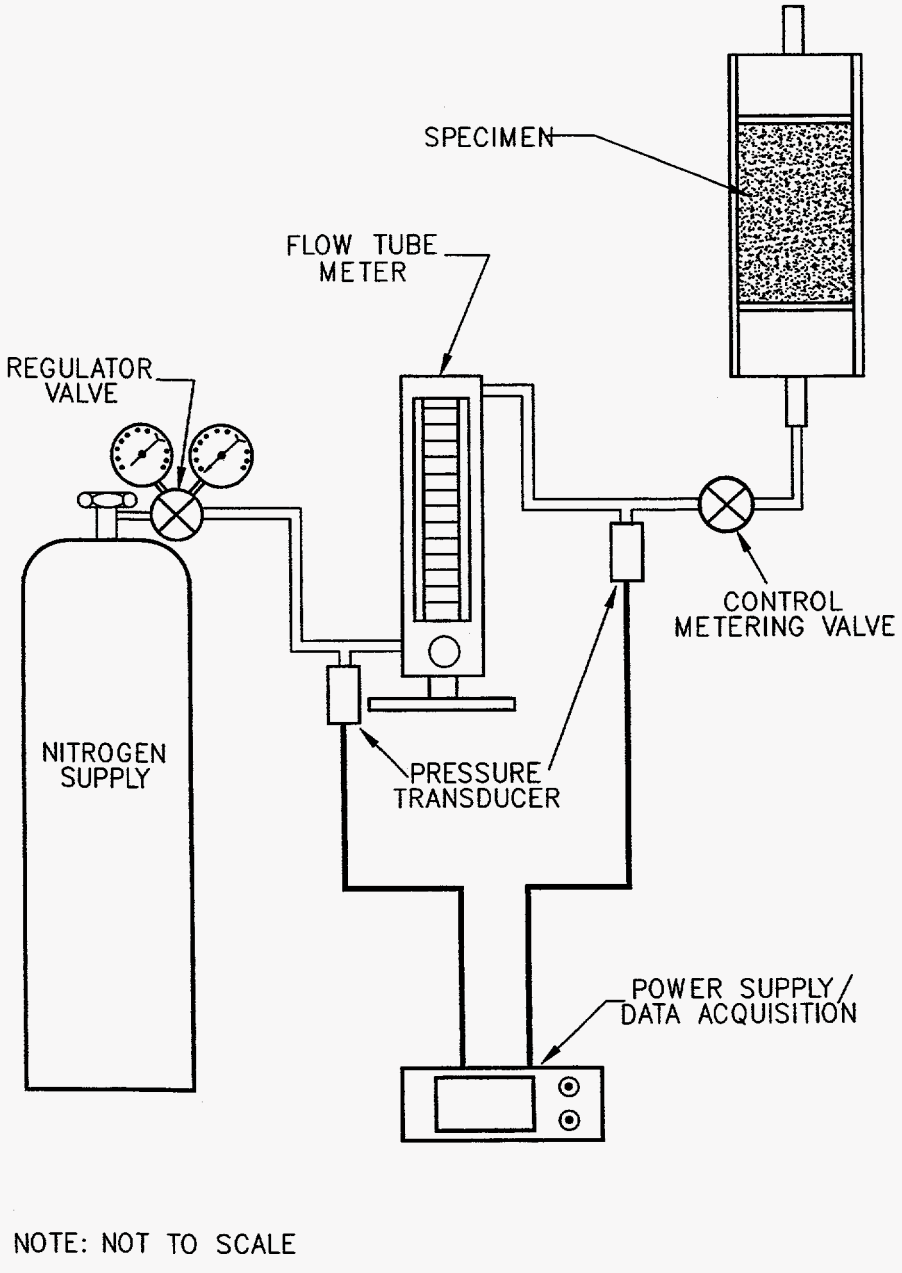

Figure 3-6. Gas permeability test setup.

2. The specimen was then hydrostatically loaded at a rate of 0.02 MPa/s. Loading continued until either of two criteria was met: (1) the fractional density had changed by a prescribed amount or (2) the hydrostatic stress had reached a prescribed level. If the first criterion was met, the specimen was unloaded to 1 MPa, reloaded to the highest stress it had attained during the hydrostatic loading stage, and then unloaded again to 1 MPa, at which time, another gas permeability measurement was performed. If the second criterion was met, the hydrostatic stress was held at its prescribed level until creep consolidation produced the desired change in fractional density. The specimen was then unloaded to 1 MPa, at which time another gas permeability measurement was performed. The hydrostatic unload-reload-unload cycle was performed to acquire data for calculating bulk modulus at the prescribed levels of fractional density.

3. Following the hydrostatic unload-reload-unload cycle and the gas permeability measurement, the specimen was subjected to a small, shear stress by increasing the axial stress to 6 MPa while maintaining the radial stress (i.e., confining pressure) at 1 MPa. The shear stress was then removed by lowering the axial stress to 1 MPa. Data collected during the shear loading/unloading were used to calculate values for Young's modulus and Poisson's ratio. Again, a gas permeability measurement was performed after the shear load cycle was completed.

4. Steps 2 and 3 were repeated until sufficient data were obtained to characterize the relationships between fractional density and gas permeability and elastic constants.

A typical load history for one specimen is shown in Figure 3-7. The load/unload cycles for both the hydrostatic and shear loading stages were of short duration (less than 1 hour), while the consolidation stages were often quite long (>5–6 days). Because the consolidation process was slow (particularly for dry specimens), hydrostatic stress levels were increased at later stages in the test so that density changes would occur more rapidly. The maximum hydrostatic stress level used to induce creep consolidation deformations was 15 MPa.

During the hydrostatic compaction/consolidation stages of the tests, current specimen density was determined from initial specimen dimensions and measurements of axial and radial strain taken during the test. Axial and radial deformations were measured using direct-contact extensometers as described previously for the constant strain-rate tests.

3.4 Petrographic Studies

Great care was taken to ensure consistency of test specimens. Specimens used in these laboratory experiments were derived from the large, dynamic-compaction demonstration initially and prepared in the laboratory later on. This section describes the microstructure of variously prepared specimens. Further descriptions are included in a memorandum included as Appendix A. In the end, consistency of grain size, moisture content, and starting density was obtained for all tested specimens. Because experimental results are controlled by these first-order specimen characteristics, features of the physical substructure are summarized here. Later in Section 4.4, petrofabrics of reconsolidated salt will be demonstrated via Scanning Electron Microscopy (SEM) and optical microscopy.

As noted earlier, several of these experiments were conducted on specimens prepared from the very large-scale, dynamic-compaction field demonstration conducted by Hansen and Ahrens. Only a few finished specimens were actually obtained from the blocks extracted from the large compacted mass. In addition to the limited number of test specimens, it was determined during the course of experimentation that the compacted mass had dehydrated from the original 1-percent water content. Therefore, it became necessary to produce alternative, similarly compacted samples in the laboratory to complete requisite experimental work.

RSI-325-96-034

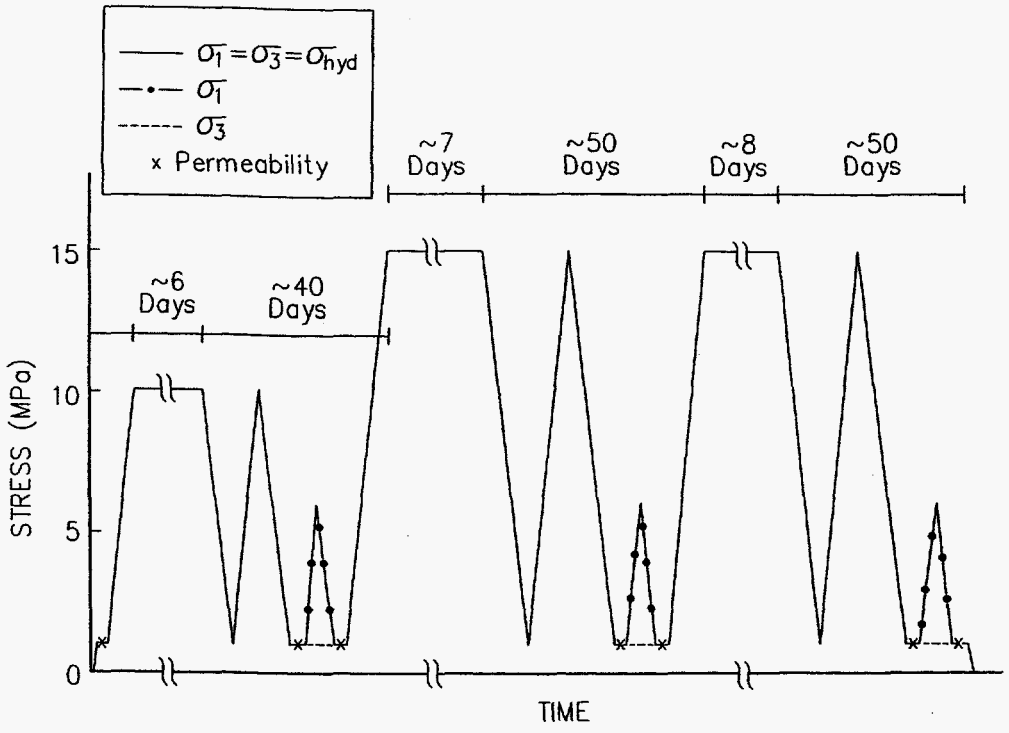

Figure 3-7. Typical load history for hydrostatic compaction and consolidation.

Specimens for SEM observations were all prepared by cutting down larger pieces into parallelepipeds having two dimensions approximately 20×20 millimeters. The sawn beam was then broken by finger pressure to produce a fresh face. This sample preparation technique was necessary because any other preparation technique, such as sawing or polishing, produces additional textures, obscuring the original. Comparisons here are made only for the substructure of the specimens before they are tested. Resultant microstructures of tested specimens are given in Section 4.4.

The characteristics of the compacted salt prepared by large-scale, dynamic compaction are examined first. Figure 3-8 (SEM numeric 0003) represents the mass of compacted grains magnified 1,100 times. Dynamically compacted salt aggregate structure has been examined and previously published (Hansen, 1997), and the heterogeneous gradation of fine particulate shown here is identical to those independent studies. Grain boundaries are open, and the relatively larger grains are abraded and blocky, rather more rounded than cleaved. Rounded abraded larger grains coupled with a significant population of fine grains indicate severe mechanical abrasion imparted by large-scale, dynamic compaction. Figure 3-9 (SEM numeric 0004) is the same material as above, shown at a magnification of only 110 times. One can observe a dense substructure comprising sorted grain sizes, with fine grains occupying available interstices.

Equivalent photomicrographs for laboratory-prepared test specimens are shown in Figures 3-10 and 3-11. At a magnification of 1,100, the ground mass comprises a well-cleaved, uniform grain size between 20 and 30 μm. Grain boundaries are open and the broken surface indicates a lack of intergranular cohesion, a feature very similar to the large-scale, dynamically compacted substructure. At 110 magnification, fine powder fills space between larger grains (up to 1 millimeter). At the lower magnification, little difference in size composition between the specimen preparation techniques can be seen.

These photomicrographs are representative of a larger population taken of several samples from the large-scale, dynamic-compaction demonstration and from laboratory-prepared samples. While laboratory-prepared samples are tailored to replicate the large-scale test fractional density (0.9) and can be prepared at an ideal water content, the texture of laboratory-prepared samples is different than that produced by large-scale, dynamic compaction. Both sample preparation processes produce a similar percentage of grains between 20 and 30 μm; however, the large-scale dynamic process produces a greater proportion of fines. Grains of laboratory-prepared specimens are cubic, as compared to more rounded, abraded grains produced by the full-scale demonstration. Based on knowledge of consolidation processes (that densification results from pressure solution/redeposition) the finer grain size produced by large-scale, dynamic compaction would be expected to increase consolidation rate relative to laboratory-prepared samples.

Other attempts to match laboratory-prepared samples to field-compacted samples were made. For example, one assembly used ten separate lifts. When the substructures of the three-lift samples, the ten-lift samples, and large-scale, dynamic compaction are compared, it is evident that the three-lift construction of test specimens is adequate for laboratory investigations (see Appendix A). Laboratory-prepared specimens are tailored to a desired moisture content, appropriate density, and a similar grain size, not withstanding the lack of fine grains. Further evidence on the adequacy of laboratory-prepared specimens is presented later when consolidated substructures are discussed.

4.0 TEST RESULTS

The experiments conducted as part of this work comprised shear consolidation testing, constant strain-rate testing, and permeability testing. The results from each of these types of testing are reported in the individual sections that follow. One additional section presents the results of the petrographic studies carried out to provide a physical description of the densification mechanisms.

4.1 Shear Consolidation

A total of eight shear consolidation tests was performed; six were performed on laboratory-scale specimens manufactured at RE/SPEC, and two were performed on specimens cored from the large-scale samples provided by Hansen and Ahrens (1998). All tests were performed at a temperature of 25°C and an axial stress difference (axial stress minus radial stress) of 4 MPa. The only controlled variable that changed among the tests was the level of radial stress (confining pressure). The test matrix for the shear consolidation tests is shown in Table 4-1. The first column in the table contains the specimen identification. The following three columns give the axial stress, radial stress, and temperature, respectively. All tests were performed in a drained condition; i.e., the ends of the specimens were vented.

Table 4-1. Shear Consolidation Test Matrix

Specimen Identification	Test Conditions		
	Axial Stress (MPa)	Radial Stress (MPa)	Temperature (°C)
RS/DCCS/1	5	1	25
RS/DCCS/3	6	2	25
RS/DCCS/4	7	3	25
RS/DCCS/5	8	4	25
RS/DCCS/10	9	5	25
RS/DCCS/15	5	1	25
DCCS/3/2/3-1	8	4	25
DCCS/3/1/2-1	8	4	25

The data acquired during the test were used to calculate principal stresses and strains according to formulas that provided true stress and true strain measures. The sign convention was that positive values indicate compression. The data reduction formulas for axial and radial strain at each data point were:

$$\varepsilon_1 = -\ln\left(\frac{L_i}{L_o}\right) \tag{4-1}$$

$$\varepsilon_3 = -\ln\left(\frac{D_i}{D_o}\right) \tag{4-2}$$

where L_o and D_o are the original length and diameter of the specimen and L_i and D_i are the current length and diameter of the specimen at any data point.

The original specimen dimensions were those measured on the bench before the specimen was encased in its protective jacket. The current specimen dimensions were determined from the deformation measurements made during the test. The change in specimen length was calculated by correcting the LVDT measurements for nonspecimen deformation; the remainder represented the axial shortening of the specimen. The change in specimen diameter was calculated from the dilatometer data after correcting for movement of the axial force ram.

The data reduction formulas for calculating true stresses used the measurements provided by the load cell and pressure transducer, and accounted for the change in specimen area. The formulas for axial and radial stresses were:

$$\sigma_1 = \frac{F - P(A_r - A_s)}{A_s} \tag{4-3}$$

$$\sigma_3 = P \tag{4-4}$$

The variables F and P represent the measured values of total axial force and confining pressure, respectively. The current area of the specimen, A_s, was calculated using the previously determined radial strain values. The area of the loading ram, A_r, was constant.

The first five tests listed in Table 4-1 were designed to investigate the effect of changes in mean stress by testing at different confining pressures while holding the axial stress difference constant. The hypothesis was that a stress state would be encountered where the radial strain rate would initially be positive (consolidation) and then reverse direction and become negative as the specimen density increased. The creep strain results for these first five tests are compared in Figures 4-1 and 4-2, which plot axial creep strain and radial creep strain, respectively, as a

function of time. In Figure 4-1, the three axial strain curves for tests performed at confining pressure above 2 MPa exhibit an inflection where the axial strain rate begins to increase. This behavior appears to be repeatable and different from the three tests performed at confining pressure of 1 and 2 MPa. No explanation is offered for this apparent pressure-sensitive behavior, but the phenomenon is being noted as a point of interest.

A significant observation is apparent in Figure 4-2 where a trend appeared in the radial strain response; that is, the radial strain rate decreases as the confining pressure increases. A very significant phenomenon was observed in the tests performed at confining pressures of 4 MPa and 5 MPa. The radial strain rate in those two tests was initially positive (specimen diameter decreasing), and after some densification of the specimen, the radial strain rate decreased and ultimately changed sign (specimen diameter increasing). This observation supports the original hypothesis that the direction of the radial strain response depends upon both the state of stress being applied and the fractional density of the specimen.

The sixth test listed in Table 4-1 was performed to replicate the radial stress test condition imposed on the first test; i.e., a confining pressure of 1 MPa. The first test seemed to exhibit very large strains as compared to the strains measured for the tests performed at higher radial stresses, so a replicate test was conducted. The two tests performed at a radial stress of 1 MPa are compared in Figures 4-1 and 4-2. As seen in the figures, the results are very comparable. The strain response at 1 MPa may result from a different mechanism, such as translation/rotation of relatively loosely packed crystals. At the higher confining pressures, the grains would be more tightly packed and densification would be dominated by pressure solution/redeposition.

The last two tests listed in Table 4-1 were performed using specimens obtained from the large compacted mass provided by the Hansen and Ahrens demonstration. These two tests were conducted to estimate the specimen-to-specimen variability in the large-scale specimens and also to compare large-scale results with laboratory-scale results. The two tests from the large-scale blocks and the single test result from the laboratory-scale specimen are given in Figure 4-3. The same test conditions were applied to all three specimens; i.e., an axial stress difference of 4 MPa and a confining pressure of 4 MPa.

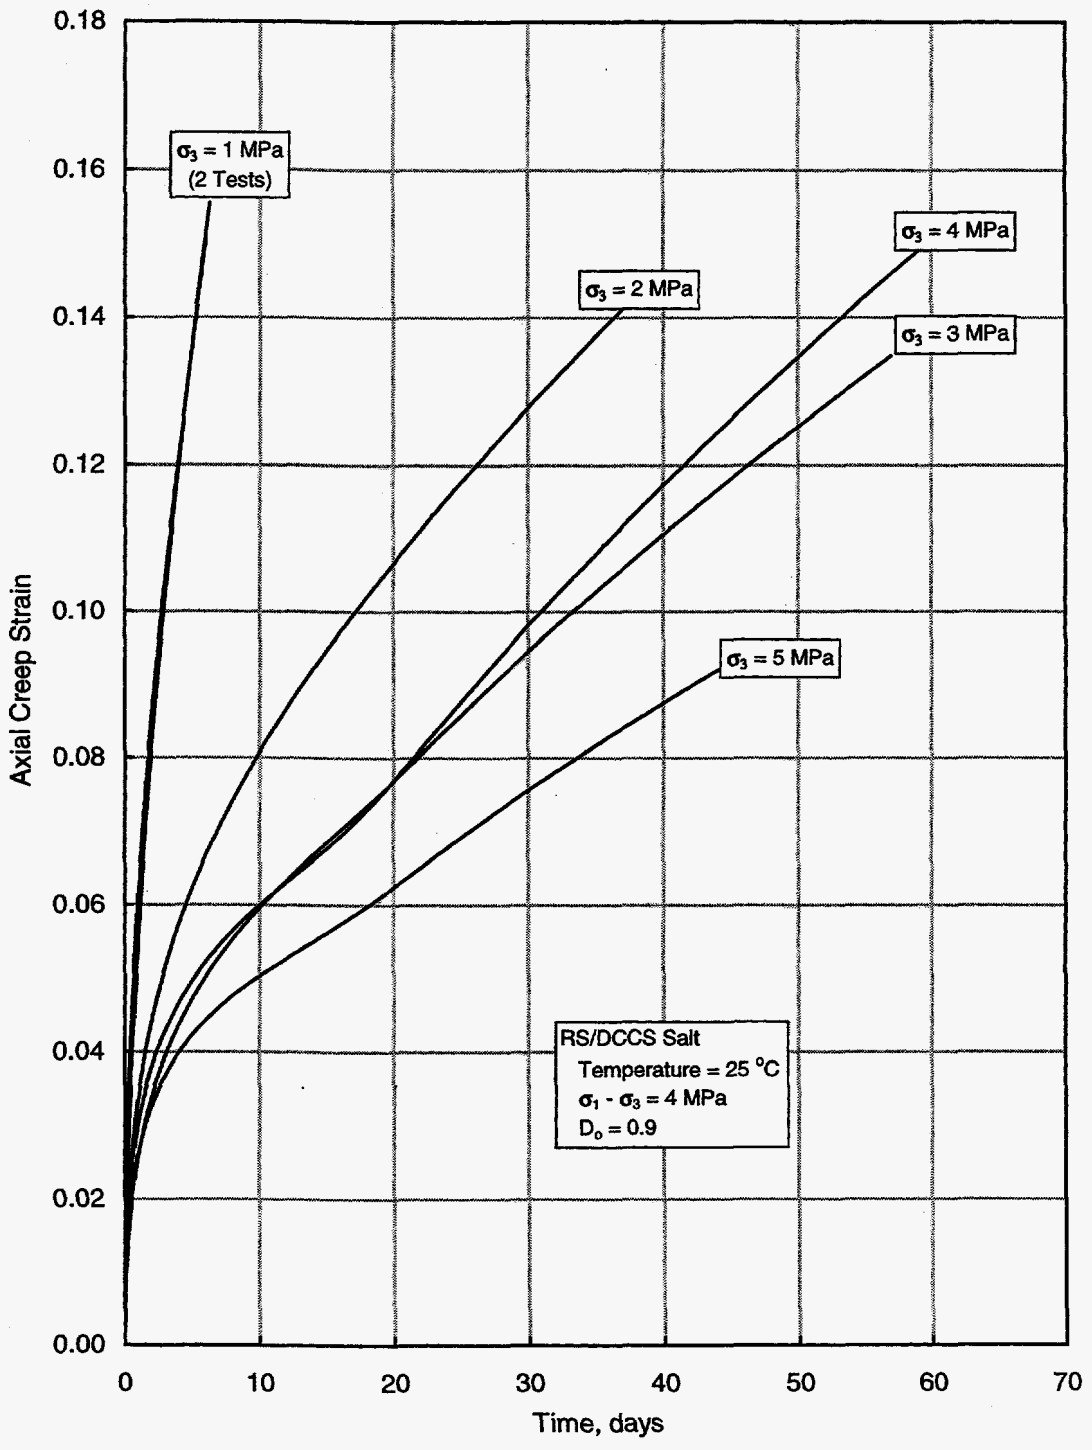

Figure 4-1. Axial creep strain as a function of time for laboratory-scale, dynamically compacted salt.

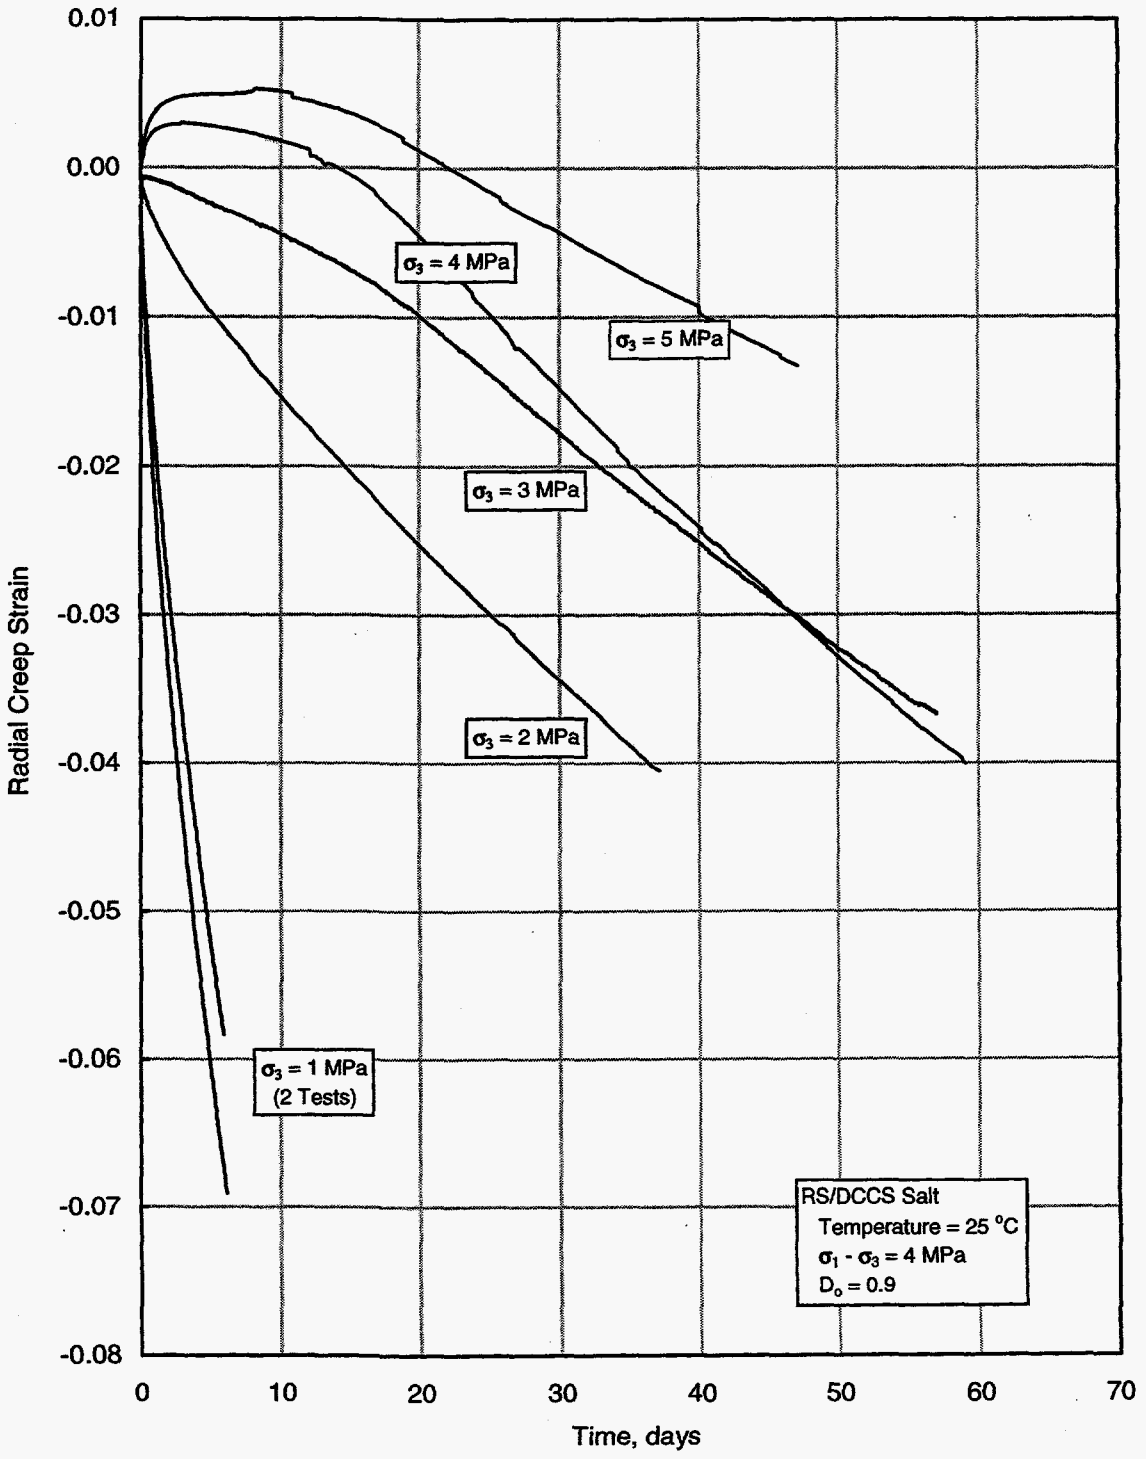

Figure 4-2. Radial creep strain as a function of time for laboratory-scale, dynamically compacted salt.

As seen in Figure 4-3, all three specimens displayed the same radial strain phenomenon; that is, the radial strain rate was initially compressive and then became extensile after some densification of the specimen. The difference between the laboratory-scale and large-scale results is likely caused by the difference in which the specimens were made. The large-scale specimens were cored from very large blocks, which were dynamically compacted as a single unit. Using that technique, it is expected that the particle size distribution of a specimen taken from the dynamically compacted mass is fairly homogeneous throughout the specimen volume. To the contrary, the laboratory-scale specimen was fabricated by dynamically compacting the crushed salt in three separate sections or lifts. This technique involved placing a third of the loose crushed salt in a mold and then compacting it by repetitive drops of a steel hammer. This process was repeated a second and third time to create a specimen of the proper length. The final product was a specimen that had two distinct zones (about ¼-inch thick) of fine crystals where the hammering took place that separated the specimen into three relatively homogeneous sections. During shear consolidation testing, the thin, fine-grain zones deformed differently than the three larger zones of coarser-grain crystals. This was apparent in post-test examination of the specimens where the fine-grain interface zones appeared as bulges. An example of the post-test profile of a typical specimen is given in Figure 4-4. The difference in deformation between the fine-grain and coarse-grain portions of the specimen was attributed to their probable difference in grain size. It is also possible that the fine-grain zones had a slightly higher fractional density at the outset. It is important to note that while the fine-grain zones may account for some difference between the laboratory-scale and large-scale results, the radial strain reversal phenomenon was observed in both types of specimens, as seen in Figure 4-3. This means that the radial-strain reversal should be seen in all types of crushed salt (assuming the proper stress state and fractional density) and is not just an experimental artifact.

Because of the post-test bulges seen in the laboratory-scale specimens, there was some concern that nonuniform deformation might have caused significant errors in the strain measurements made during the test. This concern was addressed by comparing the total inelastic strain measured during the test (the sum of stress application strains and constant stress consolidation strains) to the strain calculated as the logarithm of the ratio of post-test dimension to pre-test dimension. Those comparisons are outlined in Table 4-2 and indicate that the test system measurements were accurate. The axial strain values compare extremely favorably. The radial strain values do not compare as well as the axial strain values. This difference may be caused by the technique used to measure the specimen diameter. Two orthogonal measurements of diameter were made at 13 points along the length of the specimen. These values were then averaged to give an average specimen diameter that was used for the bench measure strain calculation. The bulges in the specimen could have a disproportionate effect on the average diameter determination, depending upon the exact locations where the measurements were made.

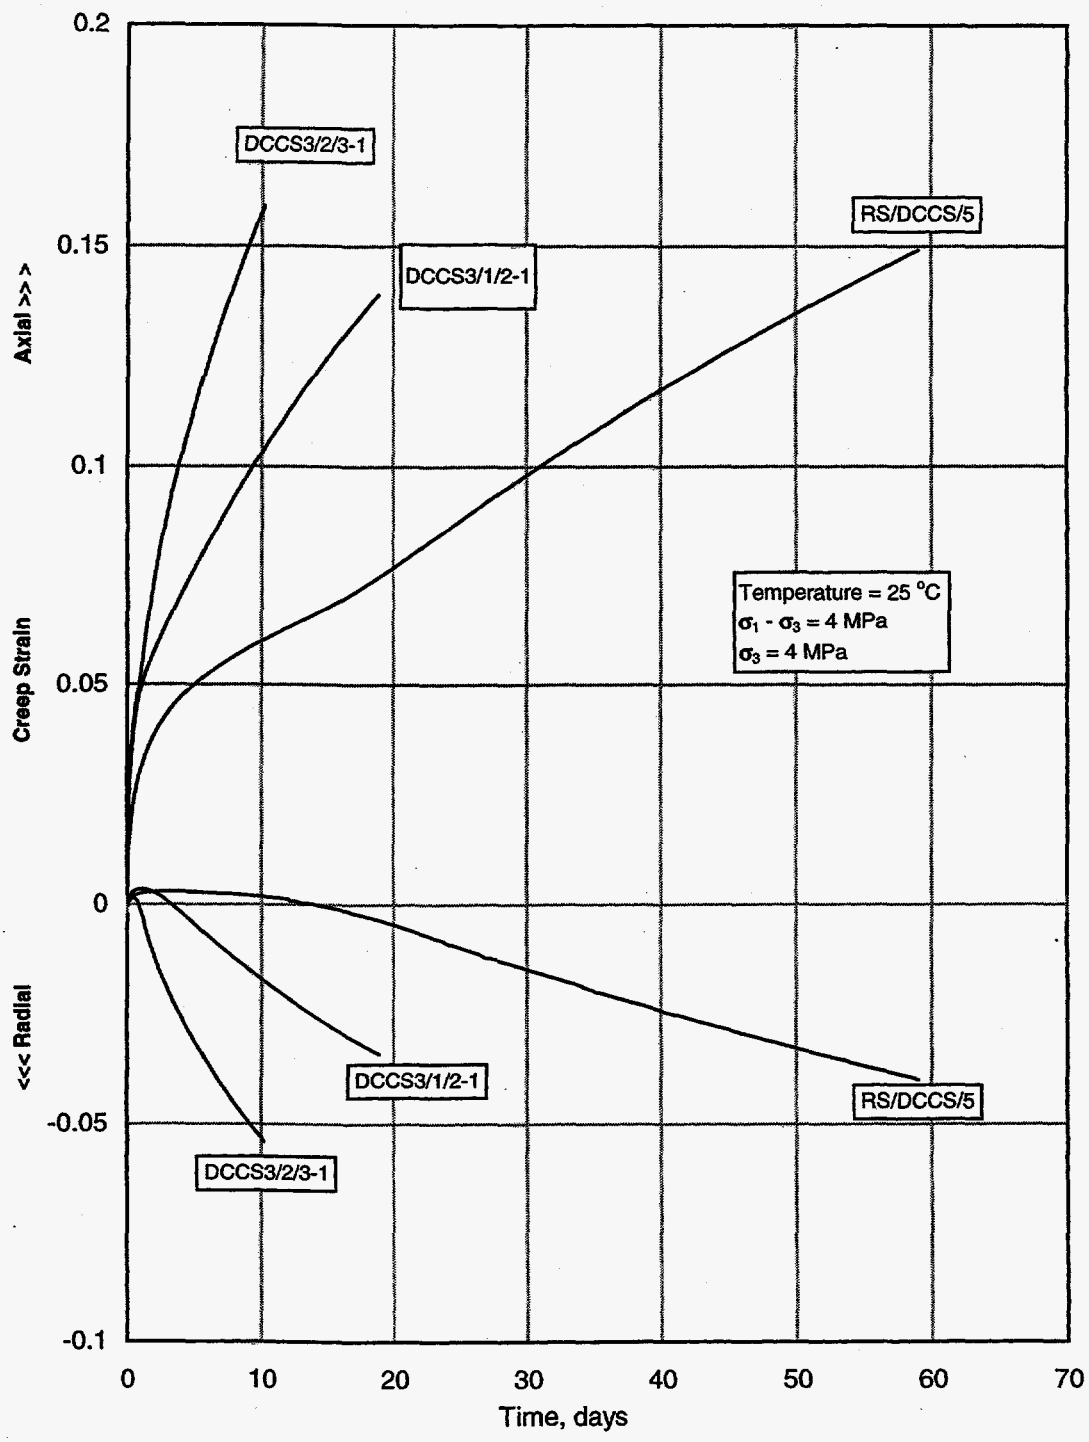

Figure 4-3. Comparison of test results from large-scale and laboratory-scale dynamically compacted salt specimens.

The effect of the bulges would be to introduce a bias in the diameter measurement, such that the post-test diameter would be overestimated, leading to an overestimation of radial strain in the bench measure calculations. Another possible explanation for the difference in radial strain measures is the existence of a leak in the test system dilatometer. A leak would cause the test measurements to underestimate the radial strain during the test. No gross leaks were detected during testing, but a small dilatometer leak could cause the relatively small differences in radial strain noted in Table 4-2.

Table 4-2. Comparison of Test System and Bench Strain Measurements

Specimen I.D.	Principal Strain Direction	Load Path Segments			Test System Total	Bench Measure Total
		Hydrostatic Pressurization	Shear Stress Application	Creep Consolidation		
RS/DCCS/1	ε_1	(a)	0.00192	0.15550	0.15742+	0.16763

	ε_3	0.00214	–0.00046	–0.05835	–0.05666	–0.06260

(a) No deformation data collected. The total system strain should have some small compressive strain added. Note that the effect would make the test system measurement lie closer to the bench measurement values.

At the termination of seven of the eight tests on dynamically compacted crushed salt, an unload/reload cycle was conducted. The data collected during the reload portion of the cycle were used to calculate estimates of the elastic constants. The data analysis was relatively simple. The slope of the axial stress difference versus axial strain curve represented Young's modulus, E. Poisson's ratio, ν, was estimated by calculating the ratio of Young's modulus to the slope of the axial stress difference versus radial strain curve. Using the estimates of E and ν, an estimate of bulk modulus, K, was then calculated from the relation $K = E / [3(1-2\nu)]$. The suite of elastic constants determined in this fashion is shown in Table 4-3. The first column contains the specimen identification and the next three columns list the elastic constant estimates. The final column lists the fractional density of the specimen at the time the unload/reload cycle was conducted.

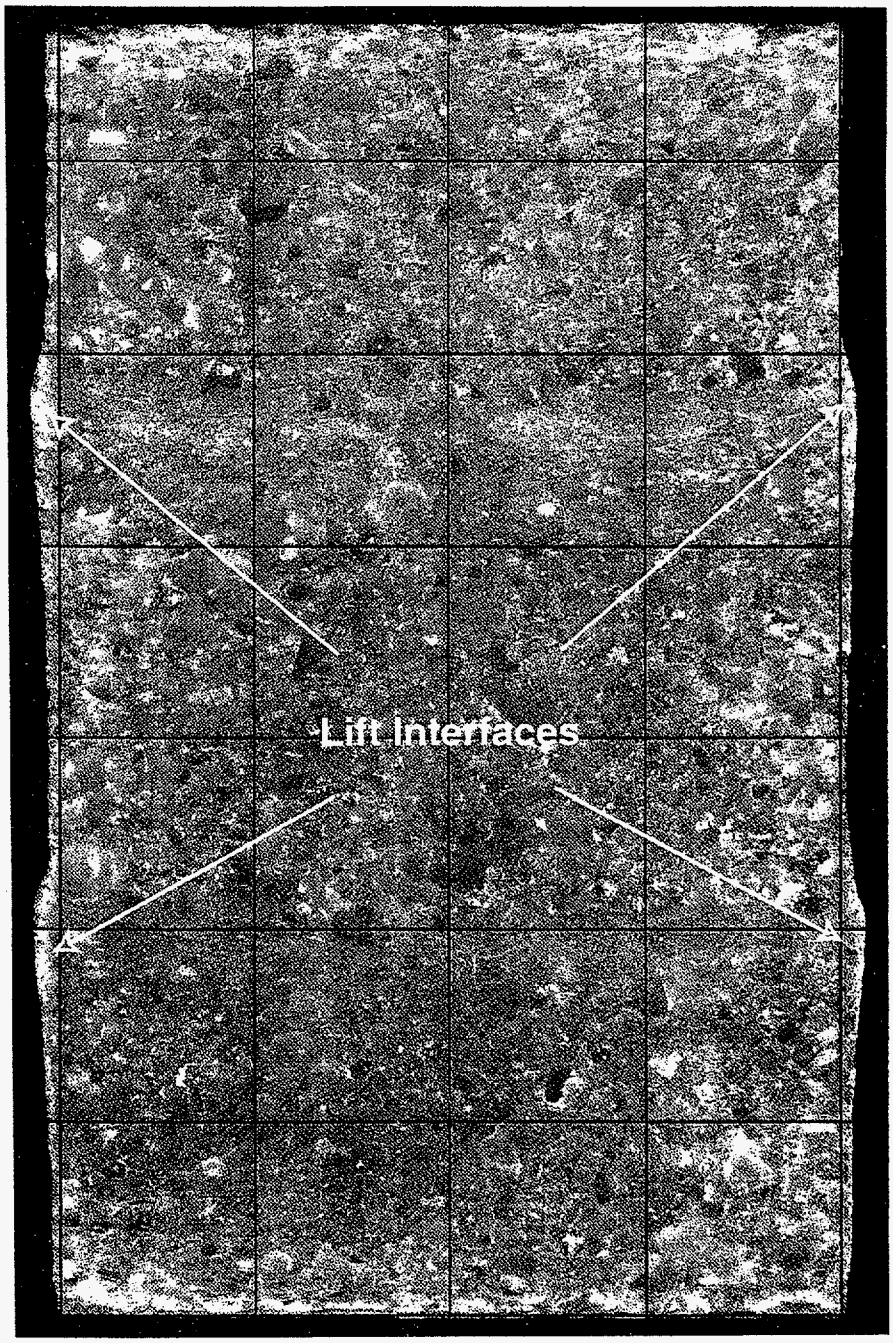

Figure 4-4. Polished half cylinder of consolidated three-lift specimen.

An inspection of the values given in Table 4-3 indicates that the elastic constants display a dependence upon the value of the fractional density of the specimen. This dependence is analyzed later at the end of Section 4.3 on permeability because additional elastic constant results were obtained during that testing.

Table 4-3. Elastic Constants for Dynamically Compacted Crushed Salt

Specimen I.D.	Young's Modulus, E (GPa)	Poisson's Ratio, ν	Bulk Modulus, K (GPa)	Fractional Density
RS/DCCS/1	N/A	N/A	N/A	N/A
RS/DCCS/3	11.7	0.303	9.9	0.971
RS/DCCS/4	13.0	0.480[(a)]	108.0	0.988
RS/DCCS/5	11.7	0.339	12.1	0.969
RS/DCCS/10	12.6	0.386	18.4	0.982
RS/DCCS/15	6.3	0.330	6.1	0.939
DCCS3/2/3-1	9.5	0.368	12.0	0.971
DCCS3/1/2-1	12.1	0.291	9.6	0.994

(a) Apparent outlier. Causes a gross increase in bulk modulus value.

4.2 Constant Strain Rate

Three constant strain-rate tests were performed on laboratory-scale specimens. The specimens were dynamically compacted using the same technique and raw crushed-salt materials that were employed for fabrication of the shear consolidation specimens. Thus, the constant strain-rate specimens had a nominal length of 200 millimeters, a nominal diameter of 100 millimeters, and a nominal fractional density of 0.9. All three tests were performed at a confining pressure of 1 MPa, a temperature of 20°C, and a constant axial strain rate. The constant axial strain rate was different for each test, as shown in Table 4-4, which is the completed test matrix. The data acquired during the tests were used to calculate principal stresses and strains according to formulas that provided true stress and true strain measures, as described for the shear consolidation tests. The sign convention was also the same; positive values indicate compression.

Table 4-4. Test Matrix for Constant Strain-Rate Experiment

Specimen I.D.	Axial Strain Rate (10^{-7} s^{-1})	Confining Pressure (MPa)	Temperature (°C)
RS/DCCS/11	0.5	1	20
RS/DCCS/6	1.0	1	20
RS/DCCS/21	2.0	1	20

Specimen RS/DCCS/6 was used to perform the first constant strain-rate test on crushed salt, and this first test served to refine the procedure outlined previously in Section 3.2.3. The first two attempts at performing this test were aborted, but the third attempt was successful and is being reported here. The first attempt was aborted because the constant strain-rate phase of the test was entered before the consolidation rates in the preceding hydrostatic phase had slowed to a value less than 1×10^{-7} s^{-1}. This caused the system to unload, as described in Section 3.2.3. The second attempt was aborted by failure of an electronic power supply in the test system shortly after the constant strain-rate phase had begun.

After determining new specimen dimensions (there was some deformation induced during the first two aborted attempts), a third attempt was successful. At the start of the third attempt, the specimen had a length of 190.3 millimeters, a diameter of 101.6 millimeters, and a fractional density of 0.92. The test duration was about 1 week, and the controlled test variables were maintained at a constant pressure of 1 MPa and a constant axial strain rate of 1×10^{-7} s^{-1} as shown in Figure 4-5 that plots the measured stresses and strains as a function of time. The plot origin represents the first data point acquired before any stresses were applied. Thus, the plot represents the entire loading history of the specimen, including the initial hydrostatic ramp up to the confining pressure of 1 MPa, the hydrostatic consolidation stage, and then the shear loading conducted at a constant axial strain rate. During the hydrostatic loading, axial strain exceeded radial strain. During the shear loading phase of the test, a small increase in compressive radial strain was measured, followed by extensile radial strains as loading continued. This appears to be a different radial strain behavior than was observed during shear consolidation creep testing at a confining pressure of 1 MPa. The fact that a small amount of compaction was observed during the initial constant strain rate shear loading may be attributed to the fact that at early loading times, the stress differences are small; whereas, in the creep tests the stress difference was 4 MPa.

The discontinuities in the axial stress measurement were traced back to a test system control problem. A multirange signal conditioner was used to measure the axial strain and that signal conditioner was adjusted for maximum sensitivity at the start of the test. As the axial strain increased, the system automatically changed to a less sensitive range. During this range switch, the closed-loop feedback circuitry is designed to operate in a "bumpless transfer" fashion; however, the system was not well tuned for these tests and a small error was introduced into the control signal during the range switch. This problem was eventually diagnosed and eliminated, but not until after all three tests in Table 4-4 were conducted, so the discontinuities in axial stress were seen in all three tests.

The other two constant strain-rate tests, RS/DCCS/11 and RS/DCCS/21, were performed without incident at axial strain rates of half and double, respectively, the strain rate used for RS/DCCS/6. The results from these two tests are shown in Figures 4-6 and 4-7, which plot the entire load history of the tests as a function of time.

The results from the three tests are compared in Figure 4-8, which plots the axial stress response from each test as a function of time. As expected, the axial stress rate is highest for the test conducted at the highest strain rate. The entire load history is plotted for each test, so they do not all start at the same point in time near the origin because of the differences in the hydrostatic consolidation duration.

Figure 4-9 plots the axial stress response of each specimen as a function of the specimen fractional density. The fractional density of the specimens was calculated using the volumetric strain data as:

$$D = \frac{\rho}{\rho_{max}} = \frac{\rho_o}{\rho_{max}(1-e_v)} \tag{4-5}$$

D is the fractional density, ρ is the current density, ρ_o is the density at the start of the test, ρ_{max} is the density of intact salt, and e_v is the engineering volumetric strain. For these calculations, the density of intact salt was 2.16 g/cc.

As seen in Figure 4-9, the axial stress response depends primarily on the fractional density of the specimen. The expectation was that a different response would be seen among the different strain-rate conditions. The fact that no large difference is seen may be attributable to the relatively small range of strain rates that was investigated.

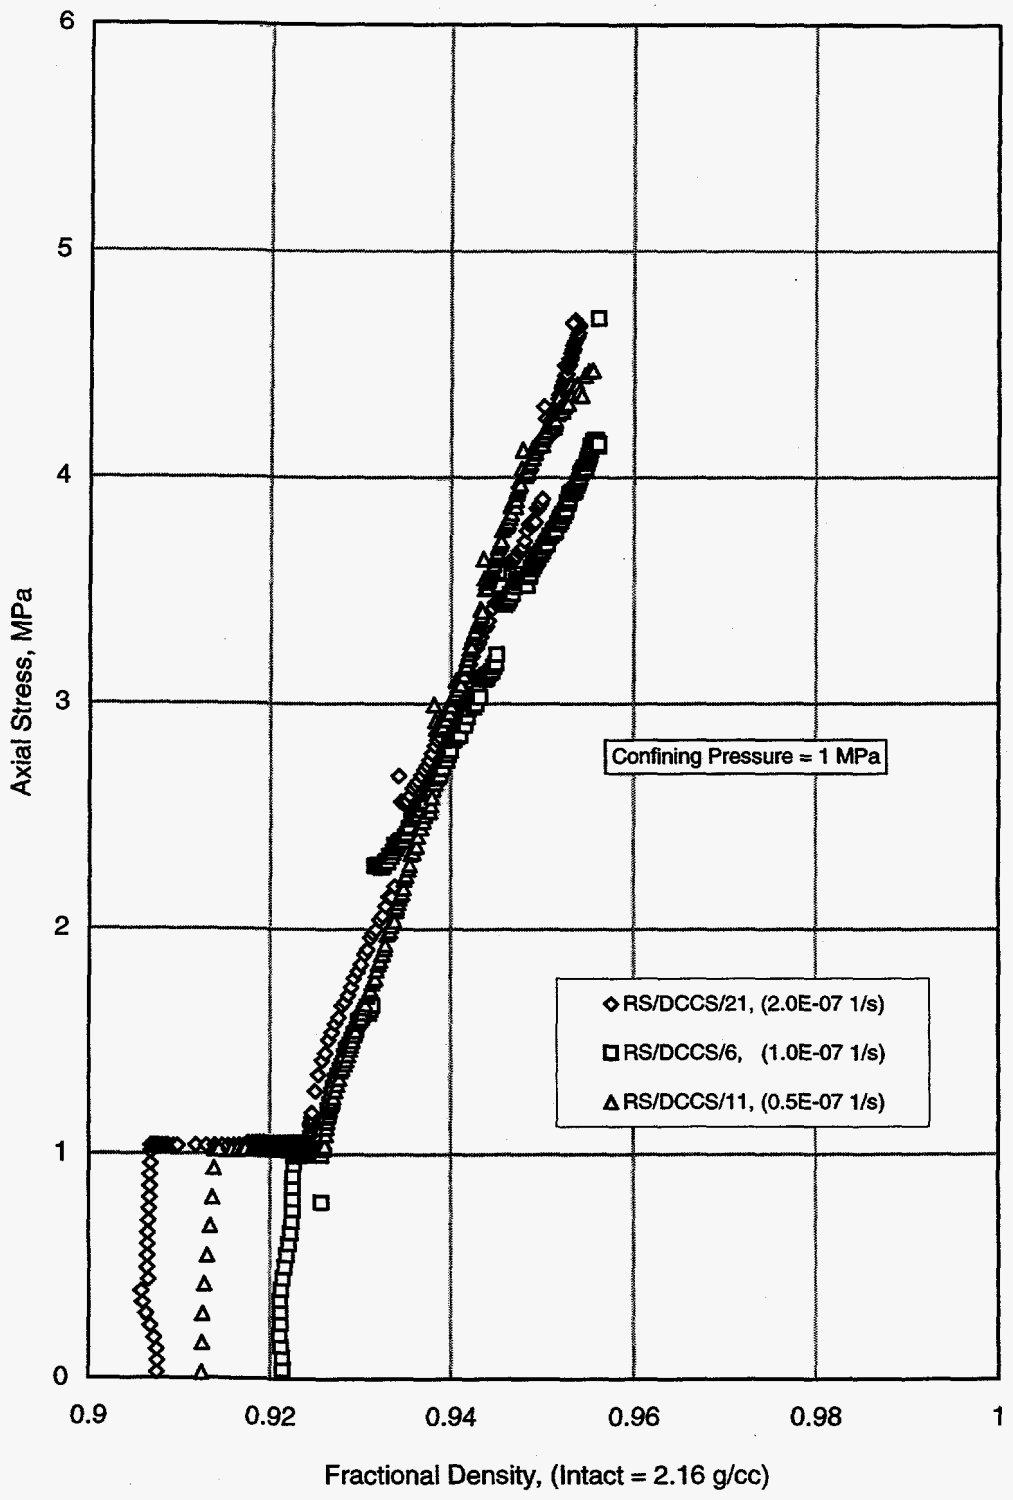

Figure 4-9. Axial stress response as a function of fractional density for three constant strain-rate tests.

4.3 Permeability

Three brine permeability tests were performed on specimens that had been previously tested for permeability using nitrogen gas. The current tests were performed at a temperature of 25°C using a hydrostatic confining stress of 1 MPa and a pore pressure of 0.345 MPa to drive the brine permeant. These test conditions were comparable to those used previously when the specimen permeability was determined using nitrogen gas as the permeant. The data reduction was based on Darcy's law as outlined by Brodsky (1994):

$$k = \frac{Q\mu L}{A\Delta P} \tag{4-6}$$

where:

k = permeability
Q = measured flow rate of brine
A = cross - sectional area of specimen
μ = brine viscosity = 1.26cP (Brodsky, 1994)
L = current specimen length
ΔP = pressure drop across the specimen.

The matrix of tests is presented in Table 4-5. The first column in the table identifies the specimen. The second and third columns contain the test conditions. The fourth column is the fractional density of the specimen at the start of the test, and the fifth column is the permeability value calculated for each specimen.

Table 4-5. Summary of Brine Permeability Experiment

Specimen I.D.	Test Conditions		Initial Fractional Density	Permeability (m^2)
	Confining Pressure (MPa)	Brine Inlet Pressure (MPa)		
DCCS/3/3/3-1	1	0.35	0.90	0[(a)]
CS/DC2/T2S-1/1	1	0.35	0.86	8.2×10^{-14}
CS/DC1/8-3	1	0.35	0.86	1.5×10^{-14}

(a) This test had an initial permeability of about 5×10^{-16} m^2. As the test progressed, the specimen consolidated and the permeability decreased to near zero.

The test on DCCS3/3/3-1 produced the data shown in Figure 4-10 that plots volumetric strain as a function of time on the primary axis and brine permeant flow as a function of time on the secondary axis. Two of the four curves in Figure 4-10 are actual test measurements; the other two are calculated. The curve labeled *Buret Measurement* is the total measured volume of brine collected at the vented end of the specimen, and the curve labeled *Volumetric Strain* is a test system measurement provided by the dilatometer. The data indicate that the saturated specimen was consolidating; thus, some volume of brine was getting expelled at the vented specimen end. This means that the buret measurement had two components. One was the volume of fluid being expelled by the action of consolidating the specimen, and the other was the volume of fluid traveling through the specimen from the pressurized brine inlet at one end of the specimen to the vented specimen end where the buret was located. Figure 4-10 implies that permeability decreases as fractional density increases. Such a relationship is reasonable, but other factors can also affect permeability without a change in fractional density. For example, under constant conditions, Brodsky (1993) reported decreasing brine permeabilities that were probably attributable to localized precipitation.

The curve labeled *Calculated Consolidation Flow* is the volume of fluid expelled from the specimen, which was calculated from the volumetric strain data. This calculation was performed by first using the relationship from Brodsky (1993) describing how the specimen density changes as a function of volumetric strain:

$$\rho_i = \rho_o \times \left(\frac{1}{1-\varepsilon_v} \right) \tag{4-7}$$

where ρ_i is the current density of the specimen, ρ_o is the original (pretest) density of the specimen, and ε_v is the engineering volumetric strain which is signed positive for compression. A second equation relates the pore space volume to the fractional density of the specimen:

$$PV_i = V_o \times \left(1 - \frac{\rho_i}{\rho_{\max}} \right) \tag{4-8}$$

PV_i is the pore space volume, V_o is the original volume of the specimen, and ρ_{max} is the density of intact salt. The ratio of the two densities is known as the fractional density of the specimen. Substituting the first equation into the second gives a relationship for the change in pore space volume as a function of the volumetric strain:

$$PV_i = V_o \times \left(1 - \frac{\frac{\rho_o}{\rho_{\max}}}{1-\varepsilon_v} \right) \tag{4-9}$$

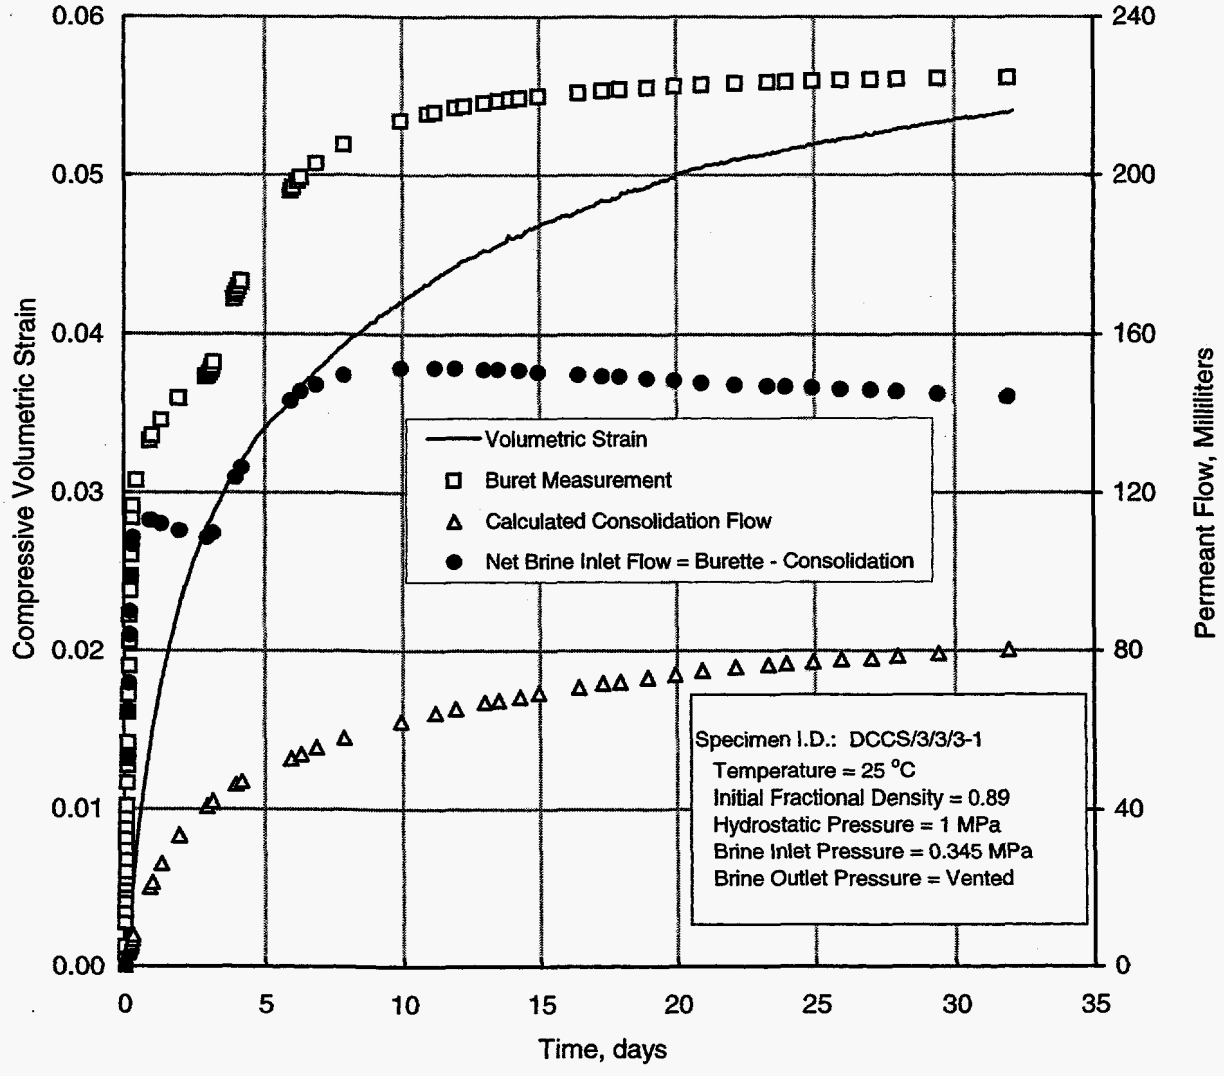

Figure 4-10. Volumetric strain and brine flow as a function of time for specimen DCCS3/3/3-1.

The curve labeled *Calculated Consolidation Flow* is the volume of fluid expelled from the specimen, which was calculated from the volumetric strain data. This calculation was performed by first using the relationship from Brodsky (1994) describing how the specimen density changes as a function of volumetric strain:

$$\rho_i = \rho_o \times \left(\frac{1}{1-\varepsilon_v} \right) \tag{4-10}$$

where ρ_i is the current density of the specimen, ρ_o is the original (pretest) density of the specimen, and ε_v is the engineering volumetric strain which is signed positive for compression. A second equation relates the pore space volume to the fractional density of the specimen:

$$PV_i = V_o \times \left(1 - \frac{\rho_i}{\rho_{\max}} \right) \tag{4-11}$$

PV_i is the pore space volume, V_o is the original volume of the specimen, and ρ_{max} is the density of intact salt. The ratio of the two densities is known as the fractional density of the specimen. Substituting the first equation into the second gives a relationship for the change in pore space volume as a function of the volumetric strain:

$$PV_i = V_o \times \left(1 - \frac{\frac{\rho_o}{\rho_{\max}}}{1-\varepsilon_v} \right) \tag{4-12}$$

Because the specimen was saturated, the volume of expelled pore fluid was calculated as the change in specimen pore volume. The volume of expelled fluid was then subtracted from the buret measurement to get the curve labeled *Net Brine Inlet Flow*. This net brine flow was the value used to calculate permeability. From inspection of the figure, it is apparent that the permeability rapidly decreased to a final value of about zero. Actually, the curve shows a small negative slope that was attributed to a combination of small measurement errors. Another possibility was that a pore pressure built up in excess of the 0.345 MPa pressure used to drive the brine through the specimen; however, such an increase would require that the vented end of the specimen was somehow plugged. The possibility of a plugged vent was checked by slowly lowering the hydrostatic confining pressure from its 1 MPa value to the 0.35 MPa brine inlet pressure value. The pressure was dropped at a rate of 0.1 MPa/minute while the buret was monitored for a change in the level of brine. The brine level remained constant until the confining pressure had decreased to the 0.35 MPa brine inlet pressure, at which time, the brine began flowing along the specimen-to-jacket interface and the buret reading began to increase. Since the brine level in the buret remained constant until the confining pressure was low enough to allow flow along the specimen-to-jacket interface, the conclusion was that the upper pore

pressure vent was not plugged during the test. Therefore, the pore pressure had not increased during the test, and permeability had diminished to zero.

The second brine permeability test was performed using Specimen CS/DC2/T2S-1/1 that had an initial fractional density of 0.86. The flow rates in this test were much higher than were observed in the first test, and the test was completed in about 1 hour. The flow versus time curve for the second test is shown in Figure 4-11, along with the calculated permeability value of 8.2×10^{-14} m^2.

The third and final brine permeability test was performed using the specimen identified as CS/DC1/8-3. The test conditions used were the same as those for the two previous brine permeability tests. The third brine permeability test had an initial fractional density of 0.86. The flow rates in this test were quite high and the accumulator used as a pressurized brine source held only about 4 liters of fluid. As a result, the accumulator was depleted in a short time, so three stages of the test were performed. Between stages, the confining pressure was reduced and the accumulator was refilled with brine. The confining pressure was then reapplied and the next stage of permeant flow was initiated. The data from the three stages were merged in chronological order and are shown in the flow versus time curve plotted in Figure 4-12. The data from the final two stages were used to calculate a permeability value of 1.5×10^{-14} m^2.

Five specimens prepared from the large-scale blocks were tested for permeability using nitrogen gas as the permeant fluid. Three of those specimens were tested at their initial fractional density (nominally 0.9) and two were mechanically deformed in a series of hydrostatic compaction/consolidation load paths so that the effect of density on permeability could be investigated. Although hydrostatic stresses of up to 15 MPa were used to increase the density of these two specimens, all permeability testing was performed at a hydrostatic stress of 1 MPa so that hydrostatic stress could be eliminated as a variable affecting the permeability measurements. Table 4-6 summarizes the permeability measurements recorded from these five specimens.

Specimen DCCS3/3/1-4 was mechanically deformed in its as-received state of moisture content; i.e., 0.44 percent. The stress and density history for this specimen is shown in Figure 4-13. For this specimen, the fractional density increased from 0.901 to 0.934 after approximately 21 days of testing and its permeability decreased from 5×10^{-14} m^2 to 5×10^{-15} m^2 over this range in fractional density.

The small change in fractional density exhibited by Specimen DCCS3/3/1-4 was attributed to the low moisture content of the specimen. Therefore, before starting the second test using Specimen DCCS3/2/2-1, the specimen was humidified to increase its moisture content to approximately the value specified in the large scale dynamic-compaction demonstration study (i.e., 1-percent). The

Table 4-6. Summary of Gas Permeability Experiment

Specimen I.D.	Fractional Density	Permeability (m^2)
DCCS3/3/3-1	0.889	7.88×10^{-14}
DCCS3/2/1-1	0.901	4.99×10^{-14}
DCCS3/1/1-4	0.889	5.51×10^{-14}
DCCS3/3/1-4	0.901	4.99×10^{-14}
	0.916	2.63×10^{-14}
	0.929	4.58×10^{-15}
	0.934	4.95×10^{-15}
DCCS3/2/2-1	0.899	8.61×10^{-14}
	0.902	6.25×10^{-14}
	0.915	3.50×10^{-14}
	0.922	2.22×10^{-14}
	0.945	5.15×10^{-15}
	0.946	7.06×10^{-16}
	0.949	8.67×10^{-17}
	0.954	2.29×10^{-16}
	0.962	9.88×10^{-17}
	0.965	1.76×10^{-16}
	0.990	6.55×10^{-21}

moisture content of Specimen DCCS3/2/2-1 was 1.27 percent after humidification. Figure 4-14 provides the stress and density history for this specimen. As shown, the fractional density increased to about 0.97 within a time of approximately 3 hours. The rapid increase in density is attributed to the addition of the small amount of moisture. The permeability for this specimen changed from approximately 8.6×10^{-14} m^2 to 6.5×10^{-21} m^2. At the high fractional densities that occurred at the end of the test on Specimen DCCS3/2/2-1, the specimen is expected to have a high brine saturation because of the moisture added before the test began. Therefore, the low gas permeability measured at the end of the test probably represents a relative permeability value rather than the true intrinsic permeability and should be used with caution.

RSI-325-98-172

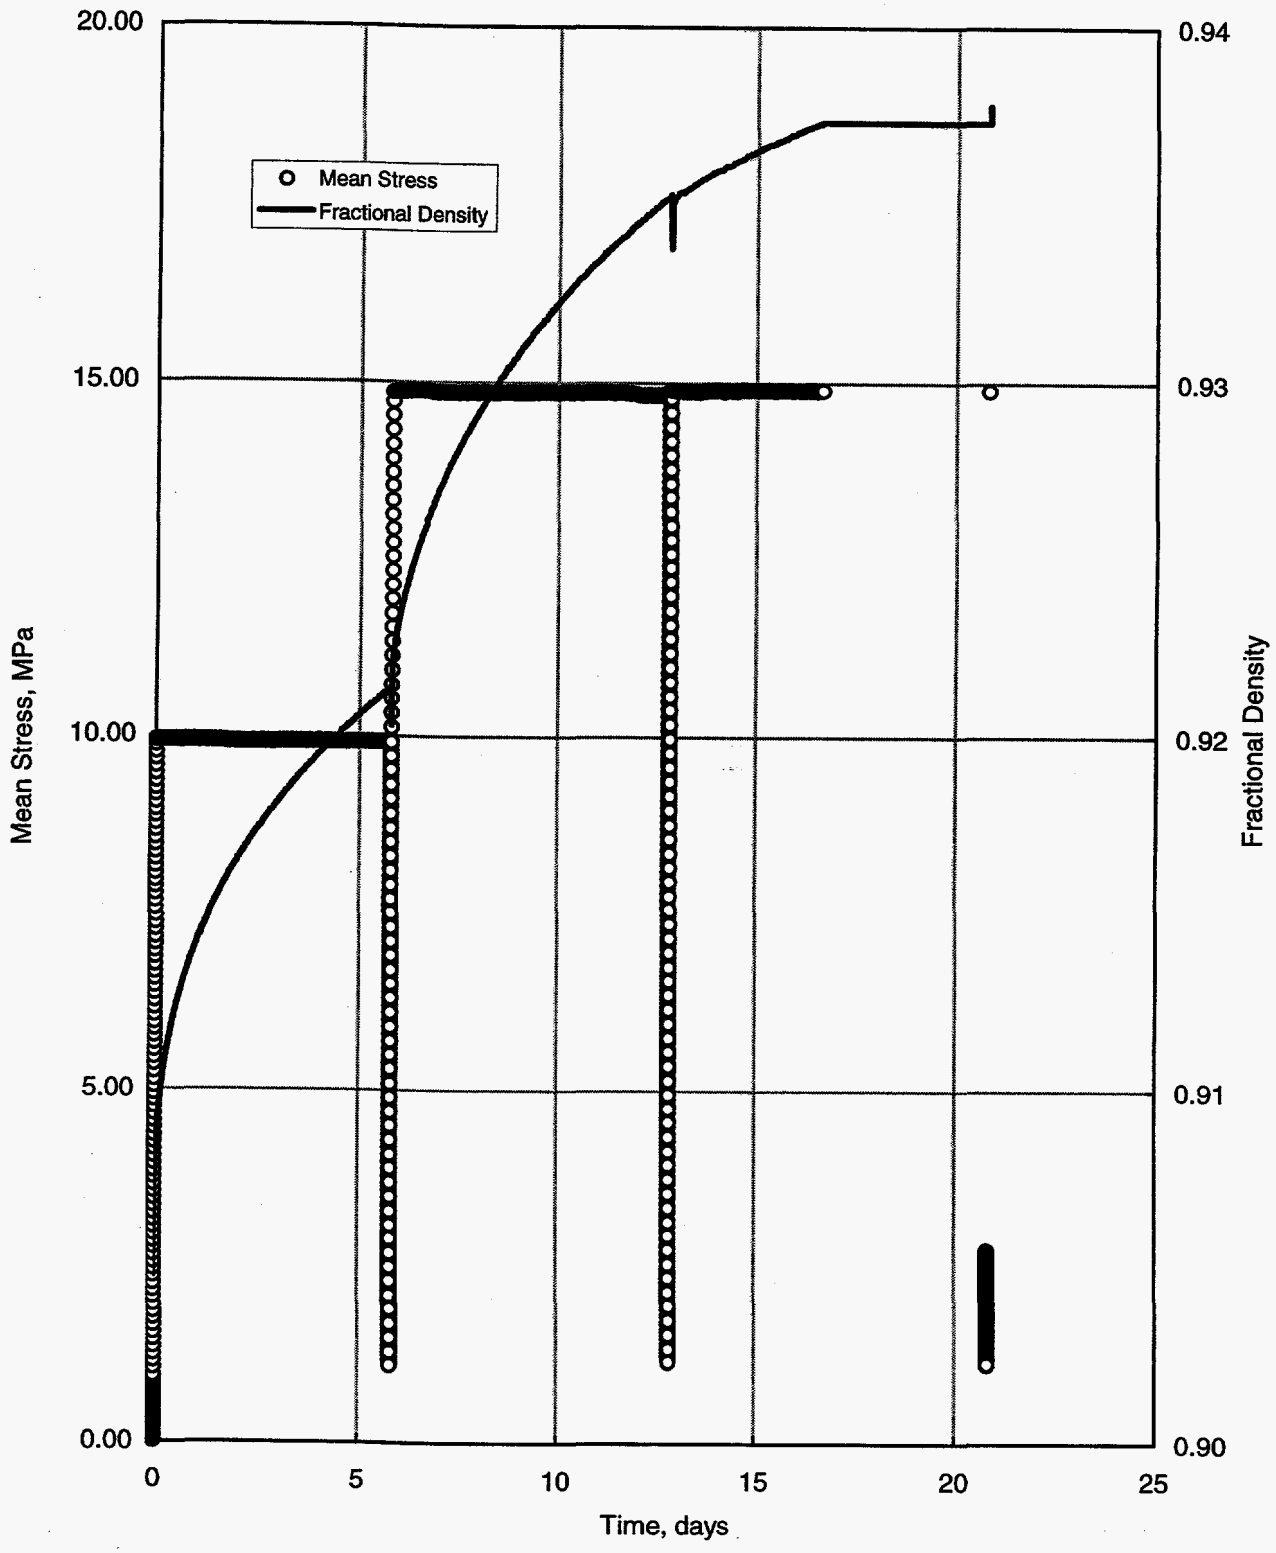

Figure 4-13. Stress and density history for permeability test on specimen DCCS3/3/1-4.

The permeability values from the three brine permeability tests (Table 4-5) and the five gas permeability tests (Table 4-6) were added to a previous database of laboratory permeability results (Appendix B) and field results generated for dynamically compacted crushed salt (Hansen and Ahrens, 1998). In compiling the combined database of permeability results, the values of fractional density reported in Appendix B were modified to account for differences in calculational methods. The fractional densities in Appendix B were calculated using the wet mass of the specimens and assuming the density of intact salt was 2.14 g/cc. The current calculations of fractional density use the dry mass of the specimen and a value of 2.16 g/cc for the density of intact salt. Thus, the fractional densities ($\overline{\rho}$) in Appendix B were corrected for water content, w, and higher density of intact salt using the expression:

$$\overline{\rho}_{2.16} = \frac{2.14}{2.16}\left(\frac{\overline{\rho}_{2.14}}{1+\frac{w}{100}}\right) \tag{4-13}$$

The moisture content for the two specimens listed as CS/DC1-4-1/3/1 and CS/DC1-8-3 in Appendix B was 0.26 percent. The moisture content for the other four specimens listed in Appendix B was 1.27 percent.

A significant difference among the permeability results was thought to be the difference in the type of permeant used. Some of the tests were performed using nitrogen gas as the permeant while the remainder of the tests used saturated brine as the permeant. The results from the two types of testing are compared in Figure 4-15, which plots permeability as a function of fractional density. As seen in the figure, the type of permeant used apparently has no major effect on the permeability determination, although the brine-based values do indicate a somewhat lower permeability than the permeability determined using gas. From only a few brine tests, statistically significant conclusions are not warranted. However, it is possible the effect results from salt precipitation at interstitial sites. A continuous decrease in brine permeability, while under constant conditions, was reported by Brodsky (1994).

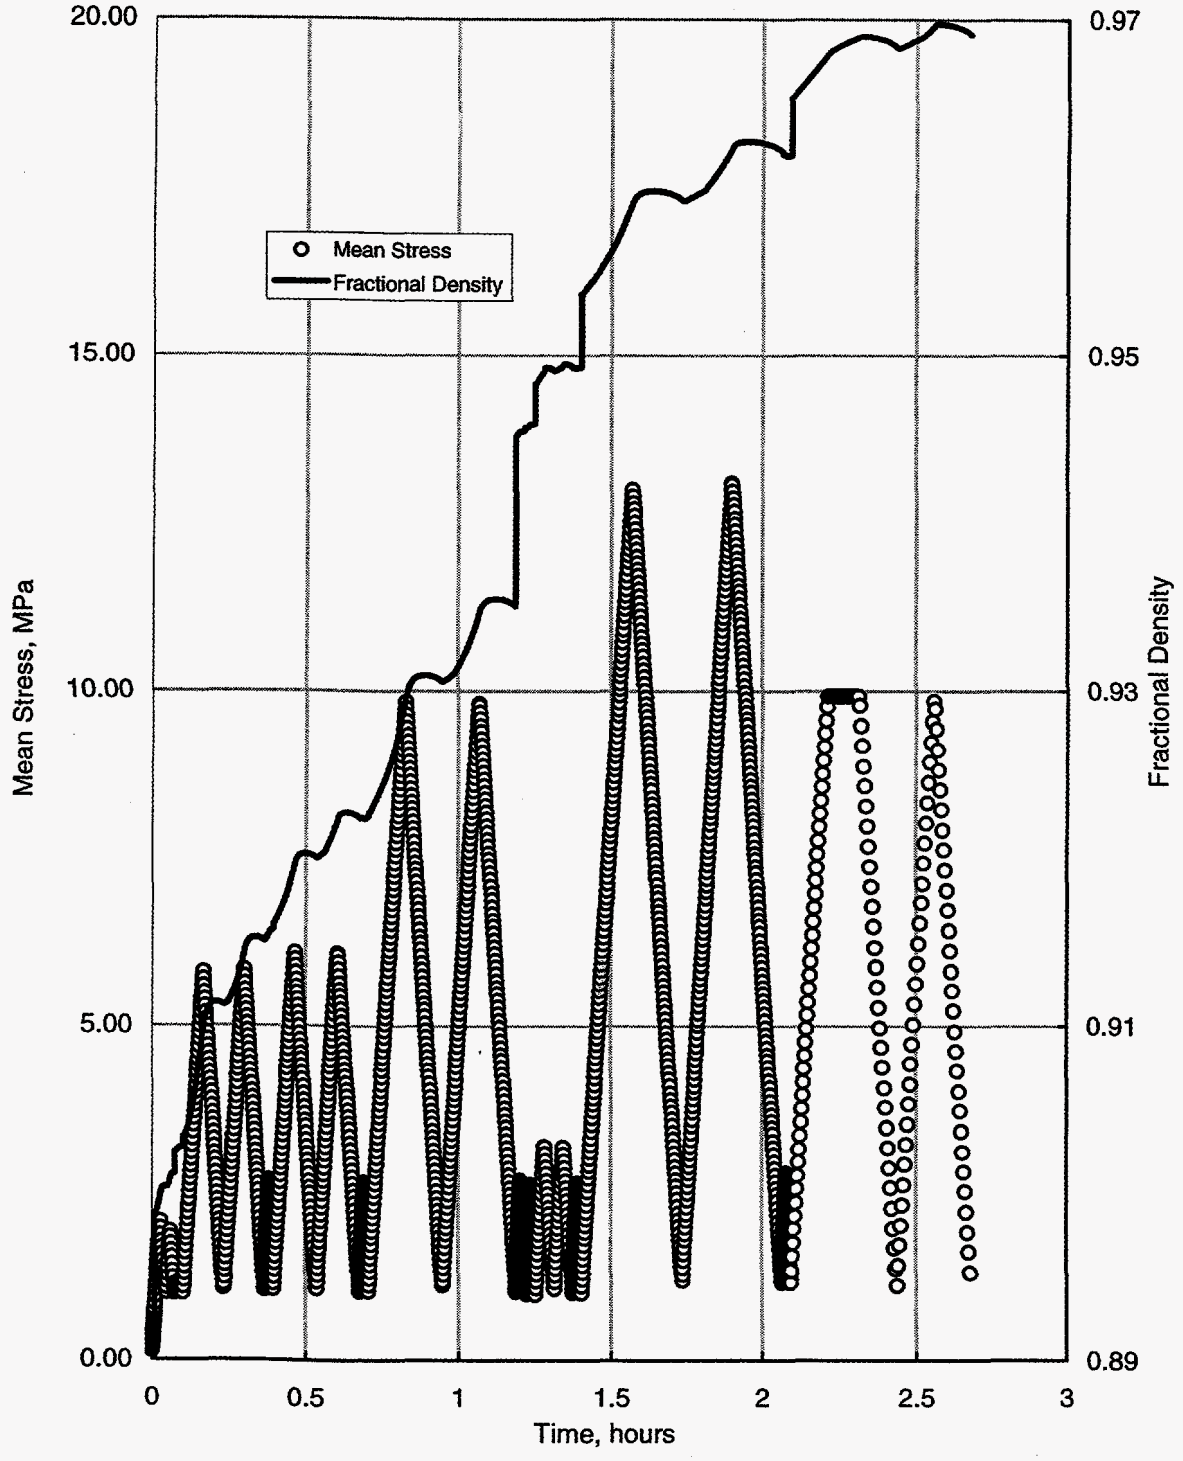

Figure 4-14. Stress and density history for permeability test on specimen DCCS3/2/2-1.

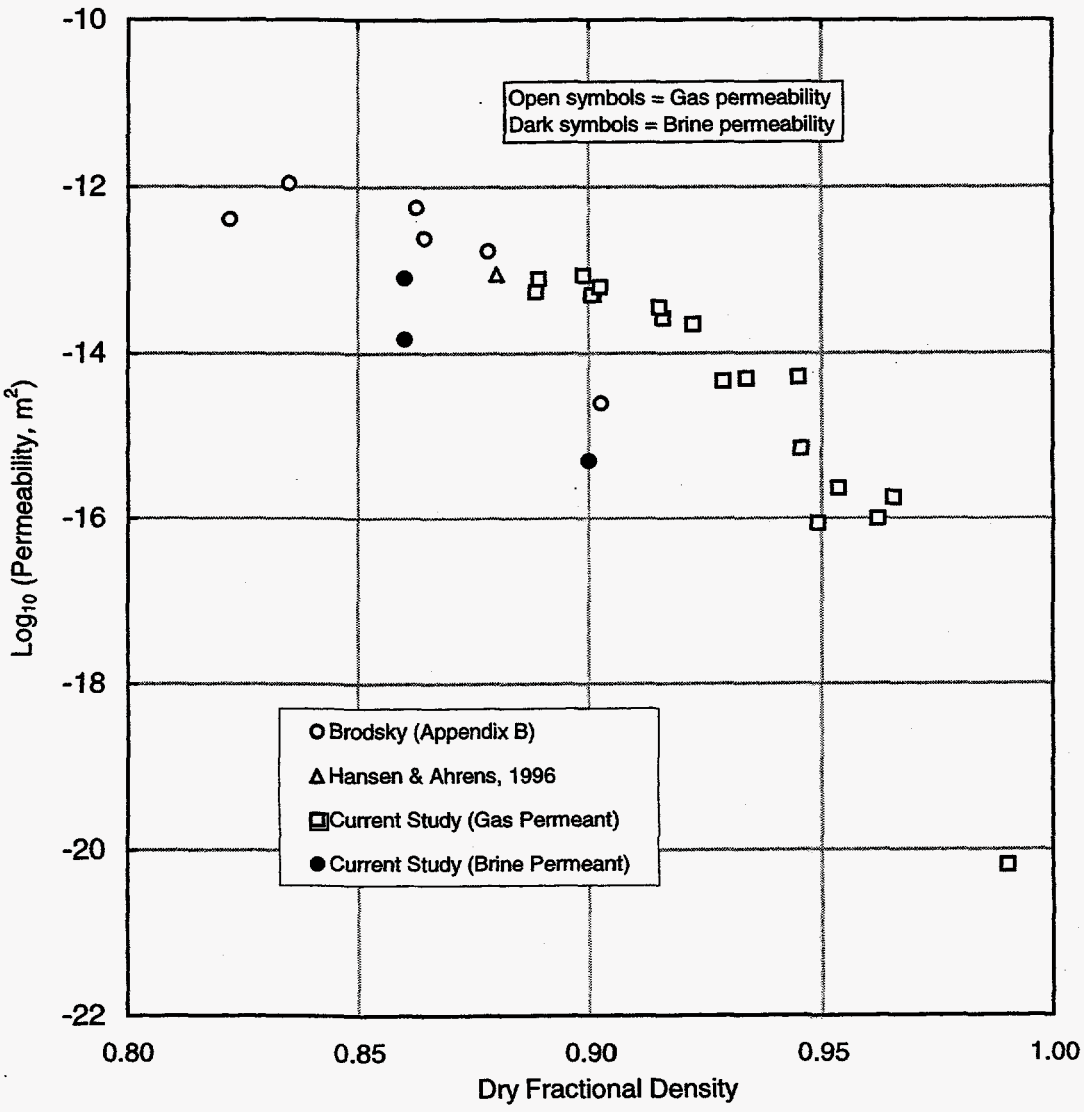

Figure 4-15. Permeability as a function of fractional density for dynamically compacted crushed salt.

Deformation data were collected from the gas permeability test on Specimen DCCS3/3/1-4 for estimating the bulk modulus, K, of the large-scale material. This provided additional information on a topic that has been investigated previously (Holcomb and Hannum, 1982); i.e., the dependence of the bulk modulus, K, on changes in fractional density. The results of the Holcomb and Hannum investigations, the test on the large-scale specimen, and the results tabulated in Table 4-3 are shown in Figure 4-16. Also shown on the figure is the value for intact salt (Munson et al., 1989). Even though the Holcomb and Hannum data were obtained using mine-run salt instead of dynamically compacted salt, the data clearly indicate that the bulk modulus of crushed salt increases nonlinearly toward the value for intact salt as the density increases. No current model was fit to describe this relationship, but a model fit by Holcomb and Hannum is shown on the figure and the current data appear to be in reasonable agreement with that model.

4.4 Substructures of Reconsolidated Crushed Salt

It has been postulated and confirmed that consolidation of granular rock salt occurs by two primary mechanisms: grain boundary pressure solution, and dislocation creep. Further, a minor amount of added moisture greatly enhances densification (Spiers and Brzesowsky, 1993). Consideration of the fundamental deformational processes guided formulation of the constitutive model for reconsolidating crushed salt (Callahan et al., 1998a). As crushed salt is loaded, the principal densification mechanism of fluid-phase grain boundary solution/redeposition is rampant. As consolidation proceeds, the material attains sufficient density that its response assumes the constitutive response of intact salt. Thus, the proper material law for reconsolidating crushed salt incorporates pressure solution and dislocation creep.

Photomicrographs of tamped and reconsolidated crushed salt, which display essential features, have been published by Brodsky et al. (1998). In this section, particular attention is given to microstructures of the reconsolidated laboratory-prepared specimens because of a unique phenomenon observed. Recall that laboratory-prepared specimens were fabricated in three lifts. Dynamic compaction, whether at the Proctor scale in the laboratory or at the full scale of construction, naturally creates more fine grain sizes at the surface than at depth in each lift. Scanning electron microscopy showed the grain size at the lift interfaces to be nearly the same as those created in the full-scale, dynamic-compaction construction demonstration (Hansen and Ahrens, 1998). Based on a considerable body of observational evidence, reconsolidation is governed by very effective pressure solution/redeposition processes occurring on the fine grains.

Figure 4-4 shows a complete cross-section of a consolidated three-lift specimen. After consolidation, the three-lift specimen actually bulged in a girdle at the lift interfaces. The reason for this behavior lies with the relatively finer grain size at the interface. The finer grain size (relative to the remainder of each lift) gives rise to more rapid grain boundary processes because

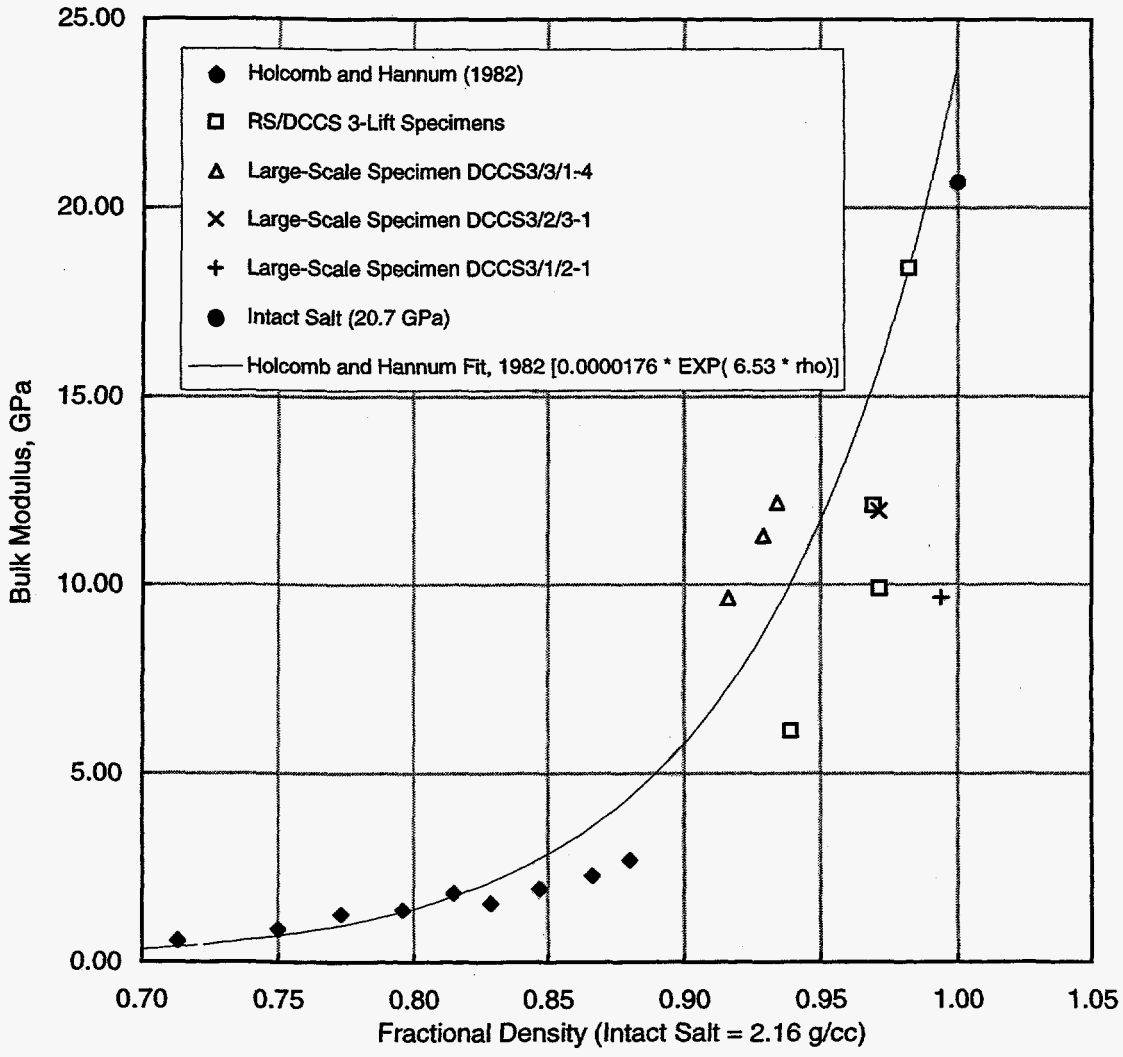

Figure 4-16. Bulk modulus as a function of fractional density.

of greater surface area available. The initial local density may also be higher than the initial average specimen density, which would also enhance the local change in consolidation mode. As the lift interface consolidates more rapidly than the rest of the specimen, the local density increases toward that of intact salt and the constitutive response changes from a consolidating mode to an intact mode. Hence, the bulges reflect locales where lateral deformation has reversed more readily from an inward direction (consolidation) to an outward direction, consistent with intact material response.

Two photomicrographs of the consolidation processes are provided in Figures 4-17 and 4-18. These examinations were made on the interface material. The first is an SEM micrograph shot at a magnification of 1,100. Note the grain size is approximately 20-30 um and almost no fine grains remain. Pressure solution is recognized by the triple junction of grains in the lower right field of view. The glossy nature of the surface is caused by cleavage fracture when the specimen surface was broken. No voids are evident, with an observation consistent with permeability diminishing to zero as consolidation approaches a fractional density of 0.95 and greater. The second is an optical micrograph with the scale bar shown on the figure. Healed grain boundaries can be discerned by the outline of fluid inclusions. Upon complete healing, these last inclusions will disappear and no optical evidence will remain of the former grain boundary. As grain boundaries heal, the very thin fluid films become isolated. These occluded fluid inclusions are displayed as the black, irregular spots in Figure 4-18. This optical photomicrograph shows the late stage of complete grain boundary healing.

5.0 CONCLUSIONS

The work documented in this report demonstrated that dynamically compacted crushed-salt specimens could be fabricated on a laboratory scale using a relatively simple device. The dynamic-compaction procedure resulted in specimens that were very similar in fractional density (0.9), water content (1.6 percent), and fabric. The similarity among specimens helped reduce the specimen-to-specimen variability in the test results.

The permeability testing of the dynamically compacted crushed salt provided further evidence that the permeability decreases as the fractional density of the salt increases. This conclusion agrees with previous results. The current test results were added to the previous database of permeability results to reinforce that conclusion.

A suite of shear consolidation creep test results were added to a database of similar results for the purpose of estimating parameters in a constitutive model that represents the behavior of crushed salt (Callahan et al., 1998a). The current testing was performed at higher initial fractional densities (0.9) and stresses (1 to 5 MPa) than were used in previous programs to give better coverage of the range of conditions likely to be encountered during sealing operations at the WIPP. The current testing provided new observations on specimen deformation that confirmed constitutive model predictions. The constitutive model predicted that stress states existed where the radial strain rate would initially be positive (consolidation) and then reverse direction and become negative as the specimen density increased. This phenomenon was clearly observed in multiple tests.

Three constant axial strain-rate tests were performed. These three tests were not to be included in the database used for estimating the parameters in the constitutive model. The purpose of these tests was to provide results from a unique load path that could be used to evaluate the predictive capability of the constitutive model.

All of the observational microscopy supports the fundamental theory of densification behavior of wet granular salt. The constitutive model developed by Callahan and coworkers embodies the governing mechanisms as documented by the enclosed micrographs. The experimental behavior is found to be consistent with theory both in the mesoscopic scale of laboratory experiments as well as the microscopic scale where the processes occur. It is the complete understanding of reconsolidation processes, verified by laboratory experiments, parameterized in one database and predicted accurately in independent experiments, comprehensively embodied in the mathematical formulation of the constitutive equations that provide the scientific basis and confidence for performance predictions of compacted-salt seal performance.
