and $y - \bar{y}$ are orthogonal and consequently Pythagoras' theory applies. The degrees of freedom indicate the number of dimensions in which the vectors are free to move. Thus before the data are collected the vector $y$ is unconstrained and has $n = 3$ degrees of freedom; the vector $\bar{y}$, which has elements $(\bar{y}, \bar{y}, \bar{y})$ and is constrained to lie on the equiangular line, has only 1 degree of freedom; the vector $y - \bar{y}$, which is constrained to lie on a plane perpendicular to $y$, has $n - 1 = 2$ degrees of freedom. The analysis of variance of Table 6B.2 conveniently summarizes these facts.

In general, each statistical model discussed in this book determines a certain line, plane or space on which if there were no error the data would have to lie. For the example of this section, for instance, the model is $y = \eta + \epsilon$. Thus, without the errors $\epsilon$, the data would have to lie on the equiangular line at some point $[\eta, \eta, \eta]$. The $t$ and $F$ criteria measure the angle that the actual data vector, which is subject to error, makes with the appropriate line, plane and space dictated by the model. The corresponding tables indicate probabilities that angles as small or smaller will occur by chance. These probabilities are dependent on the dimensions of the model and of the data through the degrees of freedom in the table.

**Generalization**

The vector breakdown of Table 6.6 for the general one-way analysis of variance is a direct extension of that of Table 6B.2. The analysis of variance of Table 6.3 is a direct extension of that of Table 6B.1. The geometry and resulting distribution theory for the general case is essentially an elaboration of that given above.

**APPENDIX 6C. MULTIPLE COMPARISONS**

Formal procedures for allowing for the effect of selection in making comparisons have been the subject of considerable research (see, e.g., O'Neill and Wetherill, 1971, and Miller, 1977, also the references listed therein).

**Confidence Interval for a Particular Difference in Means**

A confidence interval for the true difference between the means of, say, the $p$th and $q$th treatments may be obtained as follows. The observed difference $\bar{y}_p - \bar{y}_q$ has variance $\sigma^2(1/n_p + 1/n_q)$, and $\sigma^2$ is estimated by the within-treatment mean square $s^2$. Thus the estimated variance of $\bar{y}_p - \bar{y}_q$ is $s^2(1/n_p + 1/n_q)$, and a confidence interval for this single preselected difference is provided by

$$
(\bar{y}_p - \bar{y}_q) \pm t_{v, a/2} s \sqrt{\frac{1}{n_p} + \frac{1}{n_q}}
$$

(6.C1)

where $v = v_n$, the degrees of freedom associated with $s^2$.

For the example discussed in this chapter, a confidence interval for the true difference between the means of treatments $A$ and $B$ can be established as follows. We have
Experiments to Compare \( k \) Treatment Means

\[ \bar{y}_B - \bar{y}_A = 66 - 61 = 5, s^2 = 5.6 \text{ with } v = 20 \text{ degrees of freedom, } n_B = 6 \text{ and } n_A = 4, \]

and the estimated variance for \( \bar{y}_B - \bar{y}_A \) is 5.6 \( (\frac{4}{4} + \frac{1}{1}) = 2.33 \). Thus the 95\% confidence limits for the mean difference \( \eta_B - \eta_A \) are 5 \( \pm 2.09 \sqrt{2.33} \), that is, 5 \( \pm 3.2 \), where 2.09 is the value of \( t \) appropriate for 20 degrees of freedom, which is exceeded, positively or negatively, a total of 5\% of the time.

The 1 - \( \alpha \) confidence limits calculated in this way will be valid for any single chosen difference; the chance that the specific interval given above includes the true difference \( \eta_B - \eta_A \) on the stated assumptions will be equal to 1 - \( \alpha \). For \( k \) treatments, however, there are \( k(k-1)/2 \) treatment pairs, and the differences between each one of these pairs can be used to construct a confidence interval. Whereas for each interval individually the chance of including the true value is exactly equal to 1 - \( \alpha \), the chance that all the intervals will simultaneously include their true values is less than 1 - \( \alpha \).

**Tukey's Paired Comparison Procedure**

In comparing \( k \) averages, suppose that we wish to state the confidence interval for \( \eta_i - \eta_j \), taking account of the fact that all possible comparisons may be made. It has been shown by Tukey (1949) that the confidence limits for \( \eta_i - \eta_j \) are then given by

\[
(\bar{y}_i - \bar{y}_j) \pm \frac{q_{k,v/2} s}{\sqrt{2}} \sqrt{\frac{1}{n_i} + \frac{1}{n_j}}
\]

(6C.2)

where \( q_{k,v} \) is the appropriate upper significance level of the studentized range for \( k \) means, and \( v \) the number of degrees of freedom in the estimate \( s^2 \) of variance \( \sigma^2 \). This formula is exact if the numbers of observations in all the averages are equal, and approximate if the averages are based on unequal numbers of observations.

The size of the confidence interval for any given level of probability is larger when the range statistic \( q_{k,v} \) is used rather than the \( t \) statistic, since the range statistic allows for the possibility that any one of the \( k(k-1)/2 \) possible pairs of averages might have been selected for the test. Critical values of \( q_{k,v/2} \) have been tabulated; see, for instance, Pearson and Hartley (1966), Table 29. As an example, in an experimental program on the bursting strengths of diaphragms the treatments consisted of \( k = 7 \) different types of rubber, and \( n = 4 \) observations were run with each type. The data were as follows:

<table>
<thead>
<tr>
<th>treatment</th>
<th>A</th>
<th>B</th>
<th>C</th>
<th>D</th>
<th>E</th>
<th>F</th>
<th>G</th>
</tr>
</thead>
<tbody>
<tr>
<td>average ( \bar{y}_i )</td>
<td>63</td>
<td>62</td>
<td>67</td>
<td>65</td>
<td>65</td>
<td>70</td>
<td>60</td>
</tr>
<tr>
<td>variance ( s^2 )</td>
<td>9.2</td>
<td>8.7</td>
<td>8.8</td>
<td>9.8</td>
<td>10.2</td>
<td>8.3</td>
<td>8.0</td>
</tr>
</tbody>
</table>

For this example, \( k = 7 \), \( s^2 = 9.0 \), \( v = 21 \), \( \alpha = 0.05 \), and \( q_{k,v/2}/\sqrt{2} = 3.26 \); these values give for the 95\% limits

\[
\pm \frac{q_{k,v/2} s}{\sqrt{2}} \sqrt{\frac{1}{n_i} + \frac{1}{n_j}} = \pm 3.26 \sqrt{(\frac{4}{4} + \frac{1}{1})9.0} = \pm 6.91
\]

(6C.3)

MULTIPLE COMPARISONS

Thus any observed difference statistically significant likely to be real. The chance that any given treatment mean is different from the others is greater than 1 - \( \alpha \).

Dunnett's Procedure

Experimenters often want to compare the specimen means to a control specimen in the above example. Suppose we wished to compare the \( k - 1 \) treatment means to the control \( \eta_s \). For that purpose, we use Dunnett's \( t \). For the above example, we can consider the control treatment average.

\[
\pm t_{\alpha/2,v} \sqrt{\frac{Q_{k,v/2}/2}{n_s}}
\]

Therefore any observed difference statistically significant likely to be real for the special \( \alpha \) to allocate more observations \( n_s \). The ratio of the treatment averages to the control average.
Thus any observed difference greater in absolute value than 6.91 could be considered statistically significant; hence we could say that the corresponding true difference is not likely to be zero. The $7 \times 6/2 = 21$ differences are listed in the following table. Those that are statistically significant are circled. The total error rate is $\alpha = 0.05$.

\[
\begin{array}{ccccccc}
\text{treatment} & A & B & C & D & E & F & G \\
\text{average} & 63 & 62 & 67 & 65 & 65 & 70 & 60 \\
\text{difference} & \ast & -4 & -2 & -2 & \odot & 3 \\
\ast & -5 & -3 & -3 & \odot & 2 \\
\ast & 2 & 2 & -3 & \odot & 7 \\
\ast & 0 & -5 & 5 \\
\ast & -5 & 5 \\
\ast & 10 \\
\end{array}
\]

\textit{Dunnett’s Procedure for Multiple Comparisons with a Standard}

Experimenter often use a control or standard treatment as a benchmark against which to compare the specific treatments. The question then arises whether any of the treatment means may be considered to be different from the mean of the control. In the above example suppose that A was the control. The statistics of interest now are the $k - 1$ differences $\bar{y}_i - \bar{y}_A$, where $\bar{y}_A$ is the observed average response for the control treatment. The $1 - \alpha$ confidence intervals for all $k - 1$ differences from the control are as given by Equation 6C.2, except that the value of $q_{k - 1, \alpha/2}$ is replaced with Dunnett’s $t$. For tabulated values of this quantity, $t_{k - 1, \alpha/2}$, see Dunnett (1964). Thus in the above example we have $t_{6, 0.025} = 2.80$, giving for the 95% limits

\[
\pm t_{6, 0.025} \frac{1}{\sqrt{n_A}} + \frac{1}{n_i} = \pm 2.80 \times 3.00 \sqrt{\frac{1}{4} + \frac{1}{4}} = \pm 5.94 \quad (6C.4)
\]

Therefore any observed difference from the control greater than 5.94 in absolute value can be considered statistically significant. The $k - 1 = 6$ differences are as follows:

\[
\begin{array}{ccccccc}
\text{treatment} & A & B & C & D & E & F & G \\
\text{average} & 63 & 62 & 67 & 65 & 65 & 70 & 60 \\
\text{difference} & \ast & -4 & -2 & -2 & \odot & 3 \\
\end{array}
\]

Only the difference $\bar{y}_F - \bar{y}_A$ is indicative of a real difference between the means of six treatments and the control treatment.

For the special case of comparisons against a standard or a control it is good practice to allot more observations $n_A$ to the control treatment than to each of the other treatments $n_i$. The ratio $n_A/n_i$ should be approximately equal to the square root of the number of treatments, that is, $n_A/n_i = \sqrt{k}$. 

\[
(6C.3)
\]
Other Procedures

Other techniques are also available for making multiple comparisons between treatment averages. One method, to be used only if the $F$ test has shown evidence of statistically significant differences, is the Newman–Keuls (Newman, 1939, and Keuls, 1952). An alternative has been suggested by Duncan (1955). A method for constructing an interval statement appropriate for all possible comparisons among the $k$ treatments, not merely their differences, has been proposed by Scheffé (1953). The Scheffé method is the most conservative, that is, it produces the widest interval statements.

Use of Formal Tests for Multiple Comparisons

In practice it is questionable how far we should go with such formal tests. The difficulties are as follows:

1. How exact should we be about uncertainty? We may ask, for example, “How much difference does it make to know whether a particular probability is exactly 0.04, exactly 0.06, or about 0.05?”
2. Significance levels and confidence coefficients are arbitrarily chosen.
3. In addition to the procedures we have mentioned, others employ still other bases for making multiple comparisons. The subtleties involved are not easy to understand, and the experimenter may find himself provided with an exact measure of the uncertainty of a proposition he does not fully comprehend.

For many practical situations a satisfactory alternative is careful inspection of the treatment averages in relation to a sliding reference distribution, as described in this chapter. The procedure is admittedly approximate, but, we believe, not misleadingly so.
