Subject: Sparton Technology, Inc. Former Coors Road Plant Remedial Program
2010 Annual Report

Gentlemen:

On behalf of Sparton Technology, Inc. (Sparton), S.S. Papadopoulos & Associates, Inc. (SSP&A) is pleased to submit the subject report. The report presents data collected at Sparton's former Coors Road Plant during the operation of the remedial systems in 2010, and evaluations of these data to assess the performance of the systems. This report was prepared by SSP&A; Metric Corporation (Metric) collected the data that form the basis of the report and, as in past years, Metric was responsible for the operation of the remedial systems and for other field activities during 2010.

I certify under penalty of law that this document and all attachments were prepared under my direction and supervision in accordance with a system designed to assure that qualified personnel properly gather and evaluate the information submitted. Based upon my inquiry of either the person or persons who manage the system and/or the person or persons directly responsible for gathering the information, the information submitted is, to the best of my knowledge and belief, true, accurate, and complete. I further certify, to the best of my knowledge and belief, that this

document is consistent with the applicable requirements of the Consent Decree entered among the New Mexico Environment Department, the U.S. Environmental Protection Agency, Sparton Technology, Inc., and others in connection with Civil Action No. CIV 97 0206 LH/JHG, United States District Court for the District of New Mexico. I am aware that there are significant penalties for submitting false information, including the possibility of fine and imprisonment for knowing violations.

If you have any questions concerning the report, please contact me.

Sincerely,

S.S. PAPADOPULOS & ASSOCIATES, INC.

Stavros S. Papadopoulos, PhD, PE, NAE

Executive Summary

The former Coors Road Plant (Site) of Sparton Technology, Inc. (Sparton) is located at 9621 Coors Boulevard NW, Albuquerque, New Mexico. The Site is at an elevation of about 5,050 feet above mean sea level (ft MSL); the land slopes towards the Rio Grande on the east and rises to elevations of 5,150-5,200 ft MSL within a short distance to the west of the Site. The upper 1,500 feet of the fill deposits underlying the Site consist primarily of sand and gravel with minor amounts of silt and clay. The water table beneath the Site is at an elevation of 4,975-4,985 ft MSL and slopes towards the northwest to an elevation of about 4,960 ft MSL within about one-half mile of the Site. At an elevation of about 4,800 ft MSL a 2- to 3-foot clay layer, referred to as the 4800-foot clay unit, has been identified.

Investigations conducted at and around the Site in the 1980s revealed that soils beneath the Site and groundwater beneath and downgradient from the Site were contaminated. The primary contaminants were volatile organic compounds (VOCs), specifically trichloroethene (TCE), 1,1-dichloroethene (DCE), and 1,1,1-trichloroethane (TCA), and chromium. Remedial investigations that followed indicated that groundwater contamination was limited to the aquifer above the 4800-foot clay; current measures for groundwater remediation were, therefore, designed to address contamination within this depth interval.

Under the terms of a Consent Decree entered on March 3, 2000, Sparton agreed to implement a number of remedial measures. These remedial measures consisted of: (1) the installation and operation of an off-site containment system; (2) the installation and operation of a source containment system; and (3) the operation of an on-site, 400-cfm (cubic feet per minute) soil vapor extraction (SVE) system for an aggregate period of one year. The goals of these remedial measures are: (a) to control hydraulically the migration of the off-site plume; (b) to control hydraulically any potential source areas that may be continuing to contribute to groundwater contamination at the on-site area; (c) to reduce contaminant concentrations in vadose-zone soils in the on-site area and thereby reduce the likelihood that these soils remain a source of groundwater contamination; and (d) in the long-term, restore the groundwater to beneficial use.

The installation of the off-site containment system began in late 1998 and was completed in early May 1999. The system consisted of: (1) a containment well near the leading edge of the plume, designed to pump at a rate of about 225 gallons per minute (gpm), (2) an off-site treatment system, (3) an infiltration gallery in the Arroyo de las Calabacillas, and (4) associated conveyance and monitoring components. The off-site containment well began operating on December 31, 1998; except for brief interruptions for maintenance activities or due to power outages, the well has operated continuously since that date. Based on an evaluation of the performance of the system and of alternative groundwater extraction systems, conducted in 2009, Sparton recommended and the regulatory agencies approved the increase of the pumping rate of this well to about 300 gpm to accelerate aquifer restoration; this rate increase was implemented on November 3, 2010. The year 2010 was the twelfth full year of operation of this well.

The source containment system was installed during 2001 and began operating on January 3, 2002. This system consisted of: (1) a containment well immediately downgradient from the site, designed to pump at a rate of about 50 gpm, (2) an on-site treatment system, (3) six^a on-site infiltration ponds, and (4) associated conveyance and monitoring components. The year 2010 was the ninth year of operation of this well.

The 400-cfm SVE system had operated for a total of about 372 days between April 10, 2000 and June 15, 2001 and thus met the length-of-operation requirements of the Consent Decree; monitoring conducted in the Fall of 2001 indicated that the system had also met its performance goals, and the system was dismantled in May 2002.

During 2010, considerable progress was made towards achieving the goals of the remedial measures:

- The off-site containment well continued to operate during the year at an average discharge rate of 207 gpm until November 3, 2010, and an average rate of 274 gpm during the remainder of the year. Hydraulic containment of the plume was maintained under both these average pumping rates. The pumped water was treated and returned to the aquifer through the infiltration gallery. The concentrations of constituents of concern in the treated water met all the requirements of the Discharge Permit for the site.
- The source containment well continued to operate during the year at an average rate of 42 gpm, and to contain potential on-site source areas. The pumped water was treated and returned to the aquifer through the infiltration ponds. The concentrations of constituents of concern in the treated water met all the requirements of the Discharge Permit for the site.
- To address agency concerns on the potential presence of contaminants beyond the area under the hydraulic control (the capture zone) of the off-site containment well, a new monitoring well, MW-80, was installed downgradient of the leading edge of the off-site plume and beyond the capture zone of the off-site containment well. No site-related contaminants were detected in groundwater samples from this well, and the well was placed on a quarterly water-level and water-quality sampling schedule.
- Groundwater monitoring was conducted as specified in the Groundwater Monitoring Program Plan (Monitoring Plan [Attachment A to the Consent Decree]) and the State of New Mexico Groundwater Discharge Permit DP-1184 (Discharge Permit). Water levels in all accessible wells and/or piezometers, and the Corrales Main Canal were measured quarterly. Samples were collected for water-quality analyses from monitoring wells at the frequency specified in the above plan and permit and analyzed for VOCs and total chromium.
- Samples were obtained from the influent and effluent of the treatment plants for the off-site and source containment systems, and the infiltration gallery and infiltration pond

^a The performance of the six on-site infiltration ponds between 2002 and 2004 indicated that four ponds are more than adequate for handling the water pumped by the source containment well. With the approval of the regulatory agencies, Sparton backfilled two of the six ponds in 2005 to put the land to other beneficial use.

monitoring wells at the frequency specified in the Discharge Permit. All samples were analyzed for VOCs, total chromium, iron, and manganese.

- The groundwater flow and transport model that was developed in early 2000 to simulate the hydrogeologic system underlying the site and its vicinity, and which was revised several times during the past ten years was used to simulate TCE concentrations in the aquifer from start-up of the off-site containment well in December 1998 through December 2010, and to predict concentrations for December 2011. Minor adjustments were made to the model to improve its predictive capabilities in the source containment area.

The extent of groundwater contamination during 2010, as defined by the extent of the TCE plume, was essentially the same as during 2009. Of 56 wells sampled both in November 2009 and 2010, the 2010 concentrations of TCE were lower than in 2009 in 15 wells, higher in 17 wells, and remained the same in 24 wells (all below detection limits). Well MW-60, at 1,300 micrograms per liter ($\mu\text{g/L}$), continued to be the most contaminated off-site well. The corresponding results for DCE were 11 wells with lower, 5 wells with higher, and 40 wells with the same (39 below detection limits) concentrations. The TCA plume ceased to exist in 2003, and this condition continued through 2010; the highest concentration of TCA during 2010 was 4.7 $\mu\text{g/L}$ (also in well MW-60), significantly below the maximum allowable concentration of 60 $\mu\text{g/L}$ set for groundwater by the New Mexico Water Quality Control Commission.

Changes in concentrations observed in monitoring wells since the implementation of the current remedial measures indicate that contaminant concentrations in the on-site area decreased significantly. Concentrations in most off-site wells have also decreased, or remained unchanged (below detection limits). Of six wells where current concentrations are higher than they were prior to the start of the current remedial operations, the highest increase was at the off-site containment well CW-1. The concentrations of contaminants in the water pumped from CW-1 rapidly increased after the start of its operation and have remained high for several years before starting a declining trend in 2005. The high concentrations in this well and in well MW-60 indicated that areas of high concentration existed upgradient from both of these wells; however, most of the groundwater upgradient from these wells has been captured by CW-1 and concentrations both in CW-1 and MW-60 are expected to continue their declining trend.

Two of the three monitoring wells completed below the 4800-foot clay (in the Deep Flow Zone or the DFZ), well MW-67 and well MW-79, which was installed in 2006 to address the continuing presence of contaminants in DFZ monitoring well MW-71R, continued to be free of any site-related contaminants throughout 2010. Well MW-71R continued to be contaminated; however, TCE concentrations in the well declined from 210 $\mu\text{g/L}$ in August 2003 to 51 $\mu\text{g/L}$ in May 2009; during 2010, the TCE concentrations in the well ranged from 54 $\mu\text{g/L}$ in February to 67 $\mu\text{g/L}$ in August; the November 2010 TCE concentration in the well was 64 $\mu\text{g/L}$. The absence of any contaminants in MW-67 and MW-79, and the declining concentrations in MW-71R indicate that the contamination in DFZ represents a contaminated groundwater slug of limited extent. Concentration trends in MW-71R will continue to be closely monitored in the next few years to assess if there is a need for further action.

The off-site and source containment wells operated at a combined average rate of 260 gpm during 2010. A total of about 137 million gallons of water were pumped from the wells. The total volume of water pumped since the beginning of the current remedial operations on December 1998 is about 1.61 billion gallons and represents 142 percent of the initial volume of contaminated groundwater (pore volume).

A total of about 340 kilograms (kg) [750 pounds (lbs)] of contaminants consisting of about 310 kg (680 lbs) of TCE, 29 kg (64 lbs) of DCE, and 1.0 kg (2.1 lbs) of TCA were removed from the aquifer by the two containment wells during 2010. The total mass that was removed since the beginning of the of the current remedial operations through the end of 2010 is 6,210 kg (13,710 lbs) consisting of 5,820 kg (12,820 lbs) of TCE, 376 kg (830 lbs) of DCE, and 17 kg (38 lbs) of TCA. This represents about 84 percent of the total dissolved contaminant mass currently estimated to have been present in the aquifer prior to the testing and operation of the off-site containment well.

The containment systems were shut down several times during 2010 for routine maintenance activities, due to power and monitoring system failures, due to low levels in the chemical feed tanks, or due to the failure of other components of the systems. The downtime for these shutdowns ranged from 10 minutes to 195 hours; this latter shutdown of over 8 days was for replacing the pump at the off-site well in preparation of increasing its pumping rate. The rate of migration of contaminants during a shutdown (90 ft/yr) and the distance between the leading edge of the plume and the limit of the containment area of the systems (250+ ft) indicate that shutdowns of this magnitude, or of even much longer duration, do not and will not allow the escape of any contaminants beyond the containment area of the systems.

Plans for next year include continuing the operation of the off-site and source containment systems, and the collection of monitoring data as required by the plans and permits controlling system operation, groundwater discharge, and air emissions. The plugging and abandonment of monitoring wells MW-13 and MW-48 and the deepening of well MW-57, which has been approved by the agencies, will be implemented during the summer of 2011. Three other monitoring wells, which have been dry or could not be sampled because of insufficient water during the last several years, are recommended for plugging and abandonment (MW-58 and MW-61) or deepening (MW-47); this work will also be implemented if approved by the agencies. Scaling of the pipeline between the source containment well and the treatment plant appears to be the cause for reduced pumping rates from this well which is designed to pump 50 gpm. The pipeline will be cleaned in 2011 to restore the well's design pumping rate.^b

^b This task was completed on January 25, 2011, and the pumping rate of the well was restored.

PREFACE

For the last fourteen years, S. S. Papadopoulos & Associates, Inc. cooperated with Gary L. Richardson of Metric Corporation, on a variety of issues related to remedial activities at the Sparton Technology Inc.'s Former Coors Road Plant, including the preparation of the Annual Reports for the last eleven years (1999-2009). During all these years, Gary was a reliable and dependable partner who took care of containment system operation, data collection, well installation, modification and abandonment, and of other field activities. On May 12, 2011, Gary Richardson passed away after a six-month long courageous fight against a brain tumor. Gary and his dedication and contributions to the engineering profession will be missed by all who had the good fortune to cross paths with him.

Sparton Technology, Inc. and S. S. Papadopoulos & Associates, Inc. dedicate this 2010 Annual Report to the memory of **Gary L. Richardson** who contributed to the preparation of this report through his activities prior to getting sick in late 2010.

VC	Vinyl Chloride
VOC	Volatile Organic Compound

REPORT

Section 1

Introduction

The former Coors Road Plant of Sparton Technology, Inc. (Sparton) is located at 9621 Coors Boulevard NW (on the west side of the boulevard), Albuquerque, New Mexico, north of Paseo del Norte and south of the Arroyo de las Calabacillas (see Figure 1.1). Investigations conducted between 1983 and 1987 at and around the plant revealed that on-site soils and groundwater were contaminated by volatile organic compounds (VOCs), primarily trichloroethene (TCE), 1,1,1-trichloroethane (TCA) and 1,1-dichloroethene (DCE), and by chromium, and that contaminated groundwater had migrated beyond the boundaries of the facility to downgradient, off-site areas.

In 1988, the United States Environmental Protection Agency (USEPA) and Sparton negotiated an Administrative Order on Consent, which became effective on October 1, 1988. Under the provisions of this Order, Sparton implemented in December 1988 an Interim Measure (IM) that consisted of an on-site, eight-well groundwater recovery and treatment system. The initial average recovery rate of the system was about 1.5 gallons per minute (gpm); however, the recovery rate began declining within a few years due to a regional decline in water levels. As a result, the system was shut down and permanently taken out of service on November 16, 1999.

In 1998 and 1999, during settlement negotiations associated with lawsuits brought by the USEPA, the State of New Mexico, the County of Bernalillo, and the City of Albuquerque (COA), Sparton agreed to implement a number of remedial measures and take certain actions, including: (1) the installation, testing, and continuous operation of an off-site extraction well designed to contain the contaminant plume; (2) the replacement of the on-site groundwater recovery system by a source containment well designed to address the release of contaminants from potential on-site source areas; (3) the operation of a 400 cubic feet per minute (cfm) capacity on-site soil vapor extraction (SVE) system for a total operating time of one year over a period of eighteen months; (4) the implementation of a groundwater monitoring plan; (5) the assessment of aquifer restoration; and (6) the implementation of a public involvement plan. Work Plans for the implementation of the measures and actions agreed upon by the parties were developed and included in a Consent Decree entered by the parties on March 3, 2000 [Consent Decree, 2000; S.S. Papadopoulos & Associates, Inc. (SSP&A), 2000a; 2000b; 2000c; and Chandler, 2000].

The off-site containment well was installed and tested in late 1998. Based on the test results, a pumping rate of about 225 gpm was determined to be adequate for containing the off-site plume (SSP&A, 1998), and the well began operating at approximately this rate on December 31, 1998. An air stripper for treating the pumped water and an infiltration gallery for returning the treated water to the aquifer were constructed in the spring of 1999, and the well was connected to these facilities in late April 1999. In 2000, due to chromium concentrations that exceeded the permit requirements for the discharge of the treated water, a chromium reduction process was added to the treatment system and began operating on December 15, 2000; however, chromium concentrations declined in 2001 and the process was discontinued on October 31, 2001. Based on evaluations conducted in late 2009 (SSP&A, 2009b), Sparton recommended that

the pumping rate of the off-site containment well be increased to 300 gpm to expedite aquifer restoration in the off-site plume area. This recommendation was approved by USEPA and the New Mexico Environment Department (NMED) on March 26, 2010¹ and implemented by Sparton on November 3, 2010. The year 2010 constitutes the twelfth year of operation of the off-site containment system.

Sparton applied for and obtained approvals for the different permits and work plans required for the installation of the source-containment system in 1999 and 2000. The Construction Work Plan for the system was approved on February 20, 2001, and construction began soon after that date. The installation of the system was completed by the end of 2001, and the system began operating on January 3, 2002. Thus, the year 2010 constitutes the ninth year of operation of the source containment system.

SVE systems of different capacities were operated at the Sparton Facility between April and October 1998, and between May and August 1999. The 400-cfm SVE system required under the Consent Decree was installed in the spring of 2000 and operated for an aggregate of about 372 days between April 10, 2000 and June 15, 2001, meeting the one-year operation requirement of the Consent Decree. The performance of the system was evaluated by conducting two consecutive monthly sampling events of soil gas in September and October 2001, after a 3-month shut-off period. The results of these two sampling events, which were presented in the Final Report on the On-Site Soil Vapor Extraction System [Chandler and Metric Corporation (Metric), 2001] and on Table 4.7 of the 2001 Annual Report (SSP&A, 2002), indicated that TCE concentrations at all monitoring locations were considerably below the 10 parts per million by volume (ppmv) remediation goal of the Consent Decree. Based on these results, the operation of the SVE system was permanently discontinued by dismantling the system and plugging the vapor recovery well and vapor probes in May 2002.

In accordance with the requirements of the Consent Decree [Attachment D - Work Plan for the Assessment of Aquifer Restoration (SSP&A, 2000b)], a numerical groundwater flow and contaminant transport model of the aquifer system underlying the Sparton site and its vicinity was developed in 2000 and recalibrated each year until 2009. The initial development of this model is described in the 1999 Annual Report (SSP&A, 2001a), and major revisions to the model in the 2003 and 2008 Annual Reports (SSP&A, 2004; 2009a). In 2009, the model was deemed reliable for making future predictions and was used to evaluate the performance of the existing system and of several alternate groundwater extraction systems with respect to the time each system would take to restore the aquifer; based on the results of this evaluation, it was recommended that the pumping rate of CW-1 be increased to 300 gpm to accelerate aquifer restoration (SSP&A, 2009b).²

¹ Letter dated March 26, 2010 from John E. Kielling of NMED and Chuck Hendrickson of USEPA to Joseph S. Lerczak of Sparton, Re: Sentinel Well Installation Workplan Request, Sparton Technology, Inc., EPA ID No. NMD083212332.

² The report presenting the results of the evaluation (SSP&A, 2009b) was approved on July 9, 2010 (letter dated July 9, 2010 from John E. Kielling of NMED and Chuck Hendrickson of USEPA to Joseph S. Lerczak of Sparton, Re: 2007 & 2008 Annual reports Approval, Sparton Technology, Inc., EPA ID No. NMD083212332).

The purpose of this 2010 Annual Report is to:

- provide a brief history of the former Sparton plant and affected areas downgradient from the plant,
- summarize remedial and other actions taken in prior years and during 2010,
- present the data collected during 2010 from operating and monitoring systems, and
- provide interpretations of these data with respect to meeting remedial objectives.

This report was prepared by SSP&A on behalf of Sparton; Metric collected the data that form the basis of the report and, as in past years, Metric was responsible for the operation of the remedial systems and for other field activities during 2010. Background information on the site, the implementation of remedial actions, and initial site conditions as they existed prior to the implementation of the remedial actions agreed upon in the Consent Decree are discussed in Section 2; a brief summary of operations during 1999 through 2009 is included in this section. Issues related to the year-2010 operation of the off-site and source containment systems are discussed in Section 3. Data collected to evaluate system performance and to satisfy permit or other requirements are presented in Section 4. Section 5 presents interpretations of the data and discusses the results with respect to the performance and the goals of the remedial systems. A description of the site's groundwater flow and transport model and the results of evaluations made using the model are presented in Section 6. Section 7 summarizes the report and discusses future plans. References cited in the report are listed in Section 8.

Section 2

Background

2.1 Description of Facility

The site of Sparton's former Coors Road plant is approximately a 12-acre property located in northwest Albuquerque, on Coors Boulevard NW. The property is about one-quarter mile south of the Arroyo de las Calabacillas, about three-quarters of a mile north of the intersection of Coors Boulevard and Paseo del Norte, and about one-half mile west of the Rio Grande (see Figure 1.1). The property sits on a terrace about 60 feet (ft) above the Rio Grande floodplain. An irrigation canal, the Corrales Main Canal, is within a few hundred feet from the southeast corner of the property. About one-quarter mile west of the property the land rises approximately 150 ft forming a hilly area with residential properties.

The plant consisted of a 64,000-square-foot manufacturing and office building and several other small structures that were used for storage or as workshops (see Figure 2.1). Manufacturing of electronic components, including printed-circuit boards, began at the plant in 1961 and continued until 1994. Between 1994 and the end of 1999, Sparton operated a machine shop at the plant in support of manufacturing at the company's Rio Rancho plant and other locations. The property was leased to Melloy Dodge in October 1999. During 2000 and early 2001, the tenant made modifications and renovations to the property to convert it to an automobile dealership and has been operating it as a dealership since April 23, 2001.

2.2 Waste Management History

The manufacturing processes at the plant generated two waste streams that were managed as hazardous wastes: a solvent waste stream and an aqueous metal-plating waste stream. Waste solvents were accumulated in an on-site concrete sump (Figure 2.1) and allowed to evaporate. In October 1980, Sparton discontinued using the sump and closed it by removing remaining wastes and filling it with sand. After that date, Sparton began to accumulate the waste solvents in drums and disposed of them off-site at a permitted facility.

The plating wastes were stored in a surface impoundment (Figure 2.1) and wastewater that accumulated in the impoundment was periodically removed by a vacuum truck for off-site disposal at a permitted facility. Closure of the former impoundment and sump area occurred in December 1986 under a New Mexico State-approved closure plan. The impoundment was backfilled, and an asphaltic concrete cap was placed over the entire area to divert rainfall and surface-water run-on, and thus to minimize infiltration of water into the subsurface through this area.

2.3 Hydrogeologic Setting

The Sparton site lies in the northern part of the Albuquerque Basin. The Albuquerque Basin is one of the largest sedimentary basins of the Rio Grande rift, a chain of linked basins that extend south from central Colorado into northern Mexico. Fill deposits in the basin are as much

as 15,000 ft thick. The deposits at the site have been characterized by more than 100 borings advanced for installing monitoring, production, and temporary wells, and soil vapor probes, and by a 1,520 ft deep boring (the Hunters Ridge Park 1 Boring) advanced by the U.S. Geological Survey (USGS) about 0.5 mile north of the facility on the north side of the Arroyo de las Calabacillas (Johnson and others, 1996).

The fill deposits in the upper 1,500 ft of the subsurface consist primarily of sand and gravel with minor amounts of silt and clay. The near-surface deposits consist of less than 200 ft of Quaternary (Holocene and Pleistocene) alluvium associated with terrace, arroyo fan, and channel and floodplain deposits. These deposits are saturated beneath the facility and to the east of the facility toward the Rio Grande, but are generally unsaturated to the west of the site. Two distinct geologic units have been mapped in the saturated portion of these deposits: Recent Rio Grande deposits, and a silt/clay unit (Figure 2.2). The Recent Rio Grande deposits occur to the east of the facility adjacent to the Rio Grande. These deposits consist primarily of pebble to cobble gravel and sand, and sand and pebbly sand. These deposits are Holocene-age and are up to 70-ft thick. Beneath the facility, and in an approximately 1,500 ft wide band trending north from the facility, a silty clay unit has been mapped between an elevation of about 4,965 ft above mean sea level (ft MSL) and 4,975 ft MSL. This unit, which is referred to as the 4970-foot silt/clay unit, represents Late-Pleistocene-age overbank deposits. The areal extent of the unit at and in the vicinity of the Sparton site is shown in Figure 2.3. Additional information on this unit is presented in Appendix A to both the 1999 and 2000 Annual Reports (SSP&A, 2001a; 2001b). Holocene-age arroyo fan and terrace deposits, which are primarily sand and gravel, overlie this unit.

The Pliocene-age Upper Santa Fe Group (USF) deposits underlie the Quaternary alluvium. These USF deposits, to an elevation of 4,800 ft MSL, consist primarily of sand with lenses of sand and gravel and silt and clay. The lithologic descriptions of these deposits are variable, ranging from “sandy clay,” to “very fine to medium sand,” to “very coarse sand,” to “small pebble gravel.” Most of the borings into this unit were advanced using the mud-rotary drilling technique, and as a result, it has not been possible to map the details of the geologic structure. The sand and gravel unit is primarily classified as USF2 lithofacies assemblages 2 and 3 (Hawley, 1996). Locally, near the water table in some areas, the sands and gravels are classified as USF4 lithofacies assemblages 1 and 2. Lithofacies assemblages 1 and 2 represent basin-floor alluvial deposits; assemblage 1 is primarily sand and gravel with lenses of silty clay, and assemblage 2 is primarily sand with lenses of pebbly sand and silty clay. Lithofacies assemblage 3 represents basin-floor, overbank, and playa and lake deposits that are primarily interbedded sand and silty clay with lenses of pebbly sand.

At an elevation of approximately 4,800 ft MSL, a 2- to 4-foot thick clay layer is encountered. This clay layer, referred to as the 4800-foot clay unit (Figure 2.2), likely represents lake deposits. The 4800-foot clay unit was encountered in borings for seven wells (MW-67, MW-71, MW-71R, MW-79, CW-1, OB-1, and OB-2) installed during site investigations and remedial actions. The unit was also encountered in the USGS Hunter Ridge Park 1 Boring which is located about 0.5 mile north of the Sparton Site on the north side of the Arroyo de las Calabacillas. The nature of the depositional environment (i.e. lake deposits), and the fact that the unit has been encountered in every deep well drilled in the vicinity of the site, as well as at the

more distant USGS boring, indicate that the unit is areally extensive. The deposits of the Santa Fe Group immediately below the 4800-foot clay are similar to those above the clay. The USGS Hunter Ridge Park 1 Boring also indicates the presence of two other deeper clay units, a 15-foot thick unit between elevations 4,705 and 4,720 ft MSL, and a second 20-foot thick unit between elevations 4,520 and 4,540 ft MSL (see Figure 2.2).

The water table beneath the Sparton Site and between the Site and the Rio Grande lies within the Quaternary deposits; however, to the west and downgradient from the site the water table is within the USF deposits. A total of 90 wells were installed at the site to define hydrogeologic conditions and the extent and nature of groundwater contamination and to implement and monitor remedial actions; the locations of these wells are shown in Figure 2.3. Of these 90 wells, 19 have been plugged and abandoned, leaving 71 wells that are currently active at the site. Four of the existing 71 wells (MW-14R, MW-37R, MW-52R, and MW-71R) are replacements for nearby wells that became dry and were plugged and abandoned, and one well (MW-53D) was deepened after becoming dry to continue to provide data.

The off-site containment well, CW-1, and the two associated observation wells, OB-1 and OB-2, were drilled to the top of the 4800-foot clay unit and are screened across the entire saturated thickness of the aquifer above the clay unit. The source containment well, CW-2, was drilled to a depth of 130 ft and is equipped with a 50-foot screen from the water table to total depth. The monitoring wells have short screened intervals (5 to 30 ft) and were classified during their installation according to their depth and screened interval. Wells screened across, or within 15 ft of, the water table were referred to as Upper Flow Zone (UFZ) wells. Wells screened 15-45 and 45-75 ft below the water table were referred to as Upper Lower Flow Zone (ULFZ) and Lower Lower Flow Zone (LLFZ) wells, respectively.³ Wells completed below the 4800-foot clay unit were referred to as Deep Flow Zone (DFZ) wells. Wells, which were installed at locations where an ULFZ or a LLFZ well already existed and which were screened at a deeper interval than the adjacent existing well, were referred to as LLFZ or Third Flow Zone (3rdFZ) wells, regardless of the depth of their screened interval with respect to the water table.⁴ This classification, except for a few exceptions (see Footnote 4), has been maintained in this report.

The completion flow zone, location coordinates, and measuring point elevation of all existing wells are presented in Table 2.1; their diameters and screened intervals are summarized in Table 2.2. In Figure 2.4, the screened interval of each well is projected onto a schematic cross-section through the site to show its position relative to the flow zones defined above. [Monitoring wells screened in the DFZ (MW-67, MW-71R, and MW-79), wells screened across

³ This classification was based on the height of the water table as it existed in 1998 and prior years. The water table has declined since then, especially in the off-site area, at least by six ft. Because of this decline, some UFZ wells have become dry and the depth from the water table to the screened interval of ULFZ and LLFZ wells is smaller than specified in this classification.

⁴ Because of this practice, the classification of three existing monitoring wells, MW-32, MW-49, and MW-70, was not consistent with the depth of their screened intervals; well MW-32, which was completed within the ULFZ, was classified as LLFZ, and MW-49 and MW-70, which were completed within the LLFZ, were classified as 3rd FZ wells. This inconsistency was corrected during the first (1999) Annual Report prepared under the Consent Decree (SSP&A, 2001a) and, since then, MW-32 has been referred to and treated as a ULFZ well and MW-49 and MW-70 as a LLFZ well.

the entire aquifer above the 4800-foot clay (CW-1, OB-1 and OB-2), and infiltration gallery monitoring wells (MW-74, MW-75, and MW-76) are not included in this figure.]

Data collected from these wells indicate that the thickness of the saturated deposits above the 4,800-foot clay ranges from about 180 ft at the Site to about 160 ft west of the Site and averages about 170 ft. Outside the area underlain by the 4970-foot silt/clay unit, groundwater occurs under unconfined conditions; however, in the area where this unit is present, it provides confinement to the underlying saturated deposits. The water table in this area occurs within the Late-Pleistocene-age arroyo fan and terrace deposits that overlie the 4970-foot silt/clay unit and is higher than the potentiometric surface of the underlying confined portion of the aquifer.

Analyses of data from aquifer tests conducted at the Site (Harding Lawson Associates, 1992; SSP&A, 1998; 1999b) indicate that the hydraulic conductivity of the aquifer is in the range of 25 to 30 ft per day (ft/d), corresponding to a transmissivity of about 4,000 to 5,000 ft squared per day (ft²/d). A transmissivity of about 4,000 ft²/d, corresponding to a hydraulic conductivity of about 25 ft/d, is also indicated by the response of water levels to long-term pumping from the off-site containment well CW-1. Analyses of the water levels measured quarterly in observation wells OB-1 and OB-2, and in monitoring wells within 1,000 ft of the off-site containment well, indicate that the response of these wells to the long-term pumping from CW-1 is best explained with a transmissivity of 4,000 ft²/d; that is, a transmissivity of 4,000 ft²/d produces the smallest residual between calculated and measured water levels in these wells.

Water-level data indicate that the general direction of groundwater flow is to the northwest with gradients that generally range from 0.0025 to 0.006; however, within the deposits that lie above the 4970-foot silt/clay unit at the Sparton Site, the direction of groundwater flow is to the west-southwest and the water table has a steeper gradient ranging from 0.010 to 0.016. Groundwater production from the deeper aquifers and a reduction in the extent of irrigated lands in the vicinity of the Site has resulted in a regional decline of water levels. During the 1990s this regional decline averaged about 0.65 foot per year (ft/yr); the rate of decline has slowed down in the early 2000s and averaged about 0.3 ft/yr until 2007, but after a rise of about one foot in early 2007 water levels began declining at a much faster rate of 1 ft/yr or more (see well hydrographs presented in Figure 2.5 and Figure 6.3). Vertical flow is, therefore, downward with an average gradient of about 0.002.

2.4 Site Investigations and Past Remedial Actions

In 1983, several groundwater monitoring wells were installed around the impoundment and sump area to determine whether there had been a release of constituents of concern from the impoundment or the sump. Analytical results from groundwater samples taken from these wells indicated concentrations of several constituents above New Mexico State standards.

Since this initial finding in 1983, several investigations were conducted to define the nature and extent of the contamination and to implement remedial measures; these investigations continued through 1999. The results of the investigations indicated that the primary constituents of concern found in on-site soil and in both on-site and off-site groundwater were VOCs, primarily TCE, TCA and its abiotic transformation product DCE. Of these constituents, TCE had the highest concentrations and was the constituent used to define the extent of groundwater

contamination. Concentrations of DCE in groundwater were lower relative to those of TCE, but it had the second largest plume extent. Groundwater contamination by TCA was primarily limited to the facility and its immediate vicinity. Various metals were also detected in both soil and groundwater samples; of these, chromium had the highest frequency of occurrence at elevated concentrations.

During the period 1983 to 1987, Sparton worked closely with the New Mexico Environmental Improvement Division (NMEID), the predecessor to NMED. Several investigations were conducted during this period (Harding and Lawson Associates, 1983; 1984; 1985). In 1987, when it became apparent that contaminants had migrated beyond plant boundaries, the USEPA commenced negotiations with Sparton to develop an Administrative Order on Consent. This Order was signed and became effective on October 1, 1988. Under the provisions of this Order, Sparton implemented an IM in December 1988. The IM consisted of groundwater recovery through eight on-site wells (PW-1, MW-18, and MW-23 through MW-28), and treatment of the recovered water in an on-site air stripper (Figure 2.1). The purpose of this IM was to remove contaminants from areas of high concentration in the UFZ. Due to the regional decline of water levels, the total discharge rate from the IM system dropped to less than 0.25 gpm by November 1999. As a result, the system was shut down and taken permanently out of service on November 16, 1999. Groundwater production from this system, during its 11-year operation, is summarized on Table 2.3. A total of 4.4 million gallons of water were recovered during the 11-year operation period, as shown on this table.

From 1988 through 1990, horizontal and vertical delineation of the groundwater plume continued under the October 1, 1988 Order on Consent. On July 6, 1990, the first draft of the RCRA Facility Investigation (RFI) report was submitted to USEPA; the final RFI was issued on May 20, 1992 (Harding Lawson Associates, 1992) and approved by USEPA on July 1, 1992. A draft Corrective Measures Study (CMS) report was submitted to USEPA on November 6, 1992. The report was revised in response to USEPA comments, and a draft Final CMS was issued on May 13, 1996; the draft was approved, subject to some additional revisions, by USEPA on June 24, 1996. The Revised Final CMS was issued on March 14, 1997 (HDR Engineering, Inc., 1997). Nine additional monitoring wells (MW-65 through MW-73) were installed between 1996 and 1999 to delineate further the groundwater plume.

The investigations conducted at the site included several soil-gas surveys to determine the extent of groundwater contamination and to characterize vadose zone soil contamination and its potential impacts on groundwater quality. The results of soil-gas surveys conducted in 1984, 1985, 1987, and 1991 were reported in the RFI and the CMS. Additional soil-gas investigations to characterize vadose zone contamination were conducted between April 1996 and February 1997 (Black & Veatch, 1997). This work included the installation and sampling of a six-probe vertical vapor probe cluster in the source area, five vapor sampling probes at various radial distances from the former sump area, and vapor sampling of nine on-site and four off-site UFZ monitoring wells that are screened across the water table. The locations of the vapor probes (VP-1-6 and VR-1 through VR-5) and of the sampled on-site monitoring wells are shown in Figure 2.6; the locations of the sampled off-site monitoring wells MW-48, MW-57, and MW-61 are shown on Figure 2.3. The fourth off-site monitoring well, MW-37, which became dry and was plugged in 2002, was located near its replacement well MW-37R. The area where TCE

concentrations in soil-gas exceeded 10 ppmv was determined from the results of this investigation (Figure 2.7).

Following this investigation, a SVE pilot test was conducted on February 27 and 28, 1997 (Black & Veatch, 1997). The test was conducted on vapor recovery well VR-1 using an AcuVac System operating at a flow of 65 cfm at a vacuum of 5 inches of water.

Based on the results of this pilot test, an AcuVac System was installed at the site in the spring of 1998 and operated at a flow rate of 50 cfm on vapor recovery well VR-1 from April 8, 1998 to October 20, 1998 (195 days). Influent and effluent concentrations measured during the operation of the system are shown in Figure 2.8. As shown in this figure, influent TCE concentrations dropped from about 18,000 milligrams per cubic meter (mg/m^3), or about 4,000 ppmv, during the first day of operation, to about $150 \text{ mg}/\text{m}^3$ (34 ppmv) in about 120 days. Trend lines determined by analysis of the data (see Figure 2.8) indicate that influent TCE concentration was probably as low as $75 \text{ mg}/\text{m}^3$ (17 ppmv) prior to the shut-down of the system after 195 days of operation. The mass of TCE removed during this operation of the SVE system was calculated to be about 145 kilograms (kg) or 320 pounds (lbs).

2.5 Implementation of Current Remedial Actions

Based on settlement negotiations that led to the March 3, 2000 Consent Decree, Sparton agreed to implement the following remedial measures: (a) installation and operation of an off-site containment system designed to contain the contaminant plume; (b) replacement of the on-site groundwater recovery system by a source containment system designed to address the release of contaminants from potential on-site source areas; and (c) operation of a robust SVE system for a total operating time of one year over a period of eighteen months.

Implementation of the off-site containment system, as originally planned, was completed in 1999. A chromium reduction process was added to the treatment component of the system in 2000. The chromium treatment process was discontinued in 2001 because the chromium concentration in the influent dropped below the New Mexico groundwater standard. The system currently consists of:

- a containment well (CW-1) installed near the leading edge of the TCE plume;
- an off-site treatment system for the water pumped by CW-1, consisting of an air stripper housed in a building;
- an infiltration gallery installed in the Arroyo de las Calabacillas for returning treated water to the aquifer;
- a pipeline for transporting the treated water from the treatment building to the gallery;
- a piezometer, PZG-1, with an horizontal screen placed near the bottom of the gallery, for monitoring the water level in the gallery; and
- three monitoring wells (MW-74, MW-75, and MW-76) for monitoring potential water-quality impacts of the gallery.

The locations of these components of the off-site containment system are shown in Figure 2.9.

The containment well was installed in August 1998, and aquifer tests were conducted on the well and evaluated in December (SSP&A, 1998). The well began operating at a design rate of 225 gpm on December 31, 1998. During the testing of the well and during its continuous operation between December 31, 1998 and April 14, 1999, the groundwater pumped from the well was discharged into a sanitary sewer without treatment. Installation of the air stripper, the infiltration gallery, and other components of the system (except the chromium reduction process) was completed in early April, 1999. The containment well was shut down on April 14, 1999 to install a permanent pump and to connect the well to the air stripper. Between April 14 and May 6, 1999, the well operated intermittently to test the air stripper and other system components. The tests were completed on May 6, 1999, and the well was placed into continuous operation. Due to increases in chromium concentrations in the influent to, and hence in the effluent from, the air stripper, a chromium reduction process was added to the treatment system on December 15, 2000. Chromium concentrations, however, declined during 2001 and the chromium reduction process was removed on November 1, 2001. The off-site containment system is now operating with all other system components functioning.

All permits and approvals required for the implementation of the source containment system were obtained between May 1999 and February 2001. The installation of the system began soon after the approval of the Construction Work Plan for the system in February 2001, and completed in December 2001. The system was tested in December 2001 and placed into operation on January 3, 2002. The system consists of:

- a source containment well (CW-2) installed immediately downgradient of the Site;
- an on-site treatment system for the water pumped by CW-2, consisting of an air stripper housed in a building;
- six on-site infiltration ponds for returning the treated water to the aquifer;
- pipelines for transporting the pumped water to the air stripper and the treated water to the ponds; and
- three monitoring wells (MW-17, MW-77, and MW-78) for monitoring the potential water-quality impacts of the ponds.

The layout of the system is shown in Figure 2.10. The chromium concentrations in the influent to, and hence in the effluent from, the air stripper meets the New Mexico water-quality standard for groundwater and, therefore, treatment for chromium is not necessary. Based on the first three years of operation of the system, Sparton concluded that four infiltration ponds were sufficient for returning to the aquifer the water treated by this system. Therefore, in April 2005 Sparton requested USEPA and NMED approval to backfill two of the six ponds (Ponds 5 and 6 in Figure 2.10), and upon approval of this request in June 2005, the two ponds were backfilled between August and December 2005.

An AcuVac SVE system was installed on vapor recovery well VR-1 (see Figure 2.6) in the spring of 1998 and operated between April 8 and October 20, 1998. Additional SVE

operations at this location with the AcuVac system at 50 cfm and with a 200-cfm Roots blower occurred in 1999 between May 12 and June 23 and between June 28 and August 25, respectively. An additional 200-cfm Roots blower was installed in 2000, and the SVE system was operated at 400 cfm between April 10, 2000 and June 15, 2001. The total operating time during this period, 371 days and 13 hours, and the results of the performance monitoring conducted after the shut-down of the system met the requirements of the Consent Decree for the termination of the SVE operations at the site. The system was, therefore, dismantled, and the recovery well and vapor probes associated with the system were plugged in May 2002.

2.6 Initial Site Conditions

Initial site conditions, as referred to in this report, represent hydrogeologic and soil-gas conditions as they existed prior to the implementation of the current remedial measures (the installation and operation of the off-site and source containment systems, and the 1999-2001 operation of SVE systems).

2.6.1 Hydrogeologic Conditions

2.6.1.1 Groundwater Levels

The elevation of water levels in monitoring wells, based on measurements made in November 1998, is presented on Table 2.4. These data were used to prepare maps showing the configuration of the water levels at the site prior to the implementation of the current remedial measures.

Water-level data from UFZ and ULFZ well pairs indicate that UFZ wells screened above or within the 4970-foot silt/clay unit (most of the UFZ wells on the Sparton Site) have a water level that is considerably higher than that in the adjacent ULFZ wells that are screened below this unit. These water-level differences range from less than one foot near the western and southwestern limit of the unit to more than 10 ft north and northeast of the Sparton site. Outside the area underlain by the 4970-foot silt/clay unit, however, the water-level difference between UFZ and ULFZ well pairs is 0.2 foot or less. This relationship between UFZ and ULFZ water levels is illustrated in the schematic cross-section shown in Figure 2.4 (see also Figure 5.14).

In early interpretations of water-level data, including those presented in the 1999 and 2000 Annual Reports (SSP&A, 2001a; 2001b), separate water-level maps were prepared using data from UFZ, ULFZ, and LLFZ wells without taking into consideration the above-discussed relationship between the water levels in UFZ and ULFZ wells. Since the 2001 Annual Report (SSP&A, 2002), however, this relationship has been taken into consideration, and water level conditions at the site and its vicinity are presented in three maps depicting: (1) the water table above the 4970-foot silt/clay unit underlying the Sparton site and at the area north of the site, based on water-level data from UFZ wells screened above or within the silt/clay unit (referred to as the "on-site water table"); (2) the combined UFZ/ULFZ water levels based on data from UFZ and ULFZ wells outside the area underlain by the silt/clay unit (using the average water level at UFZ/ULFZ well pair locations) and ULFZ wells screened below this unit; and (3) the LLFZ water levels based on data from LLFZ wells.

The elevation of the on-site water table in November 1998 is shown in Figure 2.11. The corresponding water-level elevations in the UFZ/ULFZ and LLFZ are shown in Figures 2.12 and 2.13, respectively. These water-level maps indicate that in the off-site areas downgradient from the site, the direction of groundwater flow is generally to the northwest with a gradient of approximately 0.0025. On-site, the direction of flow is also northwesterly in both the UFZ/ULFZ and the LLFZ; however, the gradients are steeper, approximately 0.005 in the UFZ/ULFZ and 0.006 in the LLFZ. The on-site water table is affected by the on-site groundwater recovery system, which was operating during the November 1998 water-level measurements, and the presence of the 4970-foot silt/clay unit; the direction of flow changes from westerly north of the site to southwesterly on the site, with gradients that range from 0.01 to 0.016.

A discussion of water levels in the DFZ had not been included in the 2006 and earlier Annual Reports because data from only two monitoring wells (MW-67 and MW-71 or MW-71R) were available from this zone; these data indicated steep downward gradients across the 4,800-foot clay (water-level differences of about 6 feet between the LLFZ and the DFZ) but provided little information on the direction of groundwater flow in this zone. The installation of a third DFZ monitoring well (MW-79) in 2006, and the water-level data collected from the three DFZ wells between the installation of MW-79 and the end of 2008 indicate that the average direction of groundwater flow in the DFZ during this period was to the west-northwest (W 19.1° N) with an average gradient of about 0.00200 (see Figure 2.14). This direction of flow and gradient are similar to those observed in the flow zones above the 4800-foot clay.

The lower water levels in the DFZ are due to municipal and industrial pumping from the deeper horizons of the aquifer several miles to the north, west, and southwest of the Sparton site. These lower water levels and the resulting steep gradients across the 4800-foot clay unit create a potential for the downward migration of contaminants. The off-site containment well, which is fully penetrating the aquifer above the clay unit, is expected to create horizontal gradients that may counteract the downward migration potential across the clay unit.

2.6.1.2 Groundwater Quality

The concentrations of TCE, DCE, and TCA in groundwater samples obtained from monitoring wells during the Fourth Quarter 1998 sampling event are summarized on Table 2.5. Also included on this table are data obtained on September 1, 1998, from the off-site containment well, CW-1, and the nearby observation wells, OB-1 and OB-2, and from temporary wells, TW-1 and TW-2, drilled in early 1998 at the current location of MW-73 and sampled on February 18 and 19, 1998, respectively. For each of the compounds reported on Table 2.5, concentrations that exceed the more stringent of its Maximum Contaminant Level (MCL) for drinking water or its maximum allowable concentration in groundwater set by the New Mexico Water Quality Control Commission (NMWQCC) are highlighted.

These concentration data were used to prepare maps showing the horizontal extent of the TCE, DCE and TCA plumes as they existed in November 1998, prior to the beginning of pumping from the off-site containment well. The procedures presented in the Work Plan for the Off-Site Containment System were used in preparing these maps (SSP&A, 2000a). The

horizontal extent of the TCE plume (in November 1998) is shown in Figure 2.15 and the extent of the DCE and TCA plumes is shown in Figures 2.16 and 2.17, respectively. This initial extent of the plumes forms a basis for comparing their extent during the years of operation of the remedial systems that have been implemented at the site and for evaluating the effectiveness of these remedial systems.

2.6.1.3 Pore Volume of Plume

TCE is the predominant contaminant at the Sparton site and has the largest plume. Calculation of the initial volume of water contaminated above MCLs, referred to as the pore volume of the plume, was, therefore, based on the horizontal and vertical extent of the TCE plume.

In preparing the plume maps presented in the previous section (Figures 2.15 through 2.17), the completion zone of monitoring wells was not considered; that is, data from an UFZ well at one location was combined with data from an ULFZ or LLFZ well at another location. At well cluster locations, the well with the highest concentration was used, regardless of its completion zone. As such, the horizontal extent of the TCE plume shown in Figure 2.15 represents the envelope of the extent of contamination at different depths, rather than the extent of the plume at a specific depth within the aquifer.

To estimate the initial pore volume of the plume, three separate maps depicting the horizontal extent of the TCE plume were prepared using water-quality data from UFZ, ULFZ, and LLFZ monitoring wells. The concentrations measured in the fully-penetrating containment well CW-1 and observation wells OB-1 and OB-2 were assumed to represent average concentrations present in the entire aquifer above the 4800-foot clay, and these data were used in preparing all three maps. An estimate of the horizontal extent of TCE contamination at the top of the 4800-foot clay was also made by preparing a fourth plume map using the data from the containment well and the two observation wells, and data from two temporary wells that obtained samples from about 30-35 ft above the top of the clay during the construction of DFZ wells MW-67 (July 1996) and MW-71 (June 1998). [These four TCE plume maps were presented in Appendix B to both the 1999 and the 2000 Annual Reports (SSP&A, 2001a; 2001b).]

The extent of the plume based on UFZ wells was assumed to represent conditions at the water table; based on the elevation of the screened intervals in ULFZ and LLFZ wells (see Figure 2.4), the extent of the plume estimated from ULFZ wells was assumed to represent conditions at an elevation of 4,940 ft MSL, and that estimated from LLFZ wells conditions at an elevation of 4,900 ft MSL. The extent of the plume at the top of the clay was assumed to represent conditions at an elevation of 4,800 ft MSL. The area of the TCE plumes at each of these four horizons was calculated.⁵ Using these areas, the thickness of the interval between horizons, and a porosity of 0.3, the pore volume was estimated to be approximately 150 million cubic ft (ft³), or 1.13 billion gallons, or 3,450 acre-ft.

⁵ The features of the commercially available mapping program Surfer 7.0 (copyright © 1999, Golden Software, Inc.) were used in generating the plume maps and in calculating plume areas.

2.6.1.4 Dissolved Contaminant Mass

As discussed in both the 1999 and 2000 Annual Reports (SSP&A, 2001a; 2001b), calculations of the initial dissolved contaminant mass based on a plume-map approach, such as the one used above to estimate the initial pore volume (Section 2.6.1.3), significantly underestimate the dissolved contaminant mass present in the aquifer underlying the site. The calibration of the numerical transport model that was developed for the site and its vicinity (see Section 6.2.3) was, therefore, used to provide an estimate of the initial contaminant mass. During the calibration process of this model, the initial TCE concentration distribution within each model layer is adjusted, in a manner consistent with the initial concentrations observed in monitoring wells, until the computed concentrations of TCE in the water pumped from each containment well, and hence the computed TCE mass removal rates, closely match the observed concentrations and mass removal rates. Based on the calibration of the model against 1999 through 2009 water-quality data, the initial dissolved TCE mass is currently estimated to be (see Table 6.1) about 7,360 kg (16,230 lbs). Using this estimate, and ratios of the removed TCE mass to the removed DCE and TCA mass, the initial masses of dissolved DCE and TCA are estimated to be approximately 460 kg (1,010 lbs) and 22 kg (48 lbs), respectively. Thus, the total initial mass of dissolved contaminants is currently estimated to be about 7,840 kg (17,290 lbs).

2.6.2 Soil Gas Conditions

A supplemental vadose zone characterization was conducted between March 15 and May 5, 1999, which included installation and sampling of eight additional vapor probes, VP-7 through VP-14 (Figure 2.6) and resampling of 15 vapor-monitoring points that had exhibited soil-gas concentrations greater than 10 ppmv during the initial characterization. The results of the supplemental investigation are presented in Figure 2.18, with the approximate 10 ppmv TCE plume limit delineated. The extent of the TCE plume presented in this figure represents the initial conditions prior to the resumption of soil vapor extraction remedial actions in 1999.

2.7 Summary of the 1999 through 2009 Operations

During 1999 through 2009, significant progress was made in implementing and operating the remedial measures Sparton agreed to implement under the terms of the Consent Decree entered on March 3, 2000. These remedial measures resulted in the containment of the plume at the site, the removal of a significant amount of mass from the plume of groundwater contamination, and a significant reduction in soil-gas concentrations in the on-site source areas.

The remedial measures undertaken in 1999 through 2009 included the following:

- Between December 31, 1998 and April 14, 1999, and from May 6, 1999 through December 31, 2009, the off-site containment well was operated at a rate sufficient to contain the plume. The air stripper for treating the pumped water and the infiltration gallery for returning the treated water to the aquifer were constructed in the spring of 1999. These systems were connected to the containment well and tested between April 14 and May 6, 1999. A chromium reduction process was added to the off-site treatment system on December 15, 2000, to control chromium concentrations in the air stripper effluent and thus meet discharge permit requirements for the infiltration gallery; the

process was discontinued on November 1, 2001, after chromium concentrations in the influent decreased to levels that no longer required treatment.

- A 50-cfm AcuVac SVE system was operated at vapor recovery well VR-1 from May 12 through June 23, 1999, and a 200-cfm Root blower system was operated at this well from June 28 to August 25, 1999. A second 200-cfm Root blower was added to the system in the Spring of 2000, and the 400-cfm SVE system operated for a total of 372 days between April 10, 2000 and June 15, 2001 meeting the length-of-operation requirement of the Consent Decree. The results of the performance monitoring that was conducted in September and October 2001 indicated that the system had met the termination criteria specified in the Consent Decree, and the system was dismantled in May 2002.
- The source containment system, consisting of a containment well immediately downgradient from the site, an on-site treatment system, six on-site infiltration ponds, and associated conveyance and monitoring components, was installed and tested during 2001. Operation of the system began on January 3, 2002, and the system continued to operate through December 31, 2009 at a rate sufficient for containing any potential sources that may remain at the site. Two of the six infiltration ponds were backfilled in 2005 when an evaluation of the pond performance indicated that four ponds were sufficient for infiltrating the treated water.
- Groundwater monitoring was conducted as specified in the Groundwater Monitoring Program Plan, hereafter "Monitoring Plan," (Consent Decree, 2000, Attachment A) and in the State of New Mexico Groundwater Discharge Permit DP-1184 that controls the discharge of the treated water through the infiltration gallery and ponds, hereafter "Discharge Permit." Water levels in monitoring wells, containment wells, observation wells, piezometers, and the Corrales Main Canal were measured quarterly. Samples were collected for water-quality analyses from monitoring wells and from the influent and effluent of the air stripper at the frequency specified in the Monitoring Plan and the Discharge Permit, and analyzed for TCE, DCE, TCA, and other constituents, as required by these documents.
- A groundwater flow and transport model of the hydrogeologic system underlying the site was developed in 2000. The model was calibrated against data available at the end of 1999, and again against data available at the end of each subsequent year, and used to simulate TCE concentrations in the aquifer from the start-up of the containment well in December 1998 through the end of 2009. After significant modifications in early 2009, during the preparation of the 2008 Annual Report, the model was deemed reliable for making predictions of future conditions, and was used in late 2009 to evaluate alternative groundwater extraction schemes for expediting aquifer restoration (SSP&A, 2009b). Based on this evaluation, Sparton recommended that the pumping rate of the off-site containment well be increased to 300 gpm.

A total of about 1.27 billion gallons of water, corresponding to an average rate of about 219 gpm, were pumped from the off-site containment well between the start of its operation and the end of 2009. An additional total of about 0.20 billion gallons of water, corresponding to an

average rate of 48 gpm, were pumped by the source containment well between the start of its operation on January 3, 2002 and the end of 2009. The total volume of water pumped by both the off-site and source containment wells between the start of the off-site containment well operation and the end of 2009 was about 1.47 billion gallons, and represents about 130 percent of the initial volume of contaminated groundwater (pore volume). Evaluation of quarterly water-level data indicated that the off-site containment well maintained control of the off-site contaminant plume throughout each year, and that the source containment well developed a capture zone that contains potential on-site source areas that may be contributing to groundwater contamination.

The total mass of contaminants that was removed by the off-site containment well between the start of its operation and the end of 2009 was about 5,645 kg (12,460 lbs) and consisted of 5,310 kg (11,710 lbs) of TCE, 320 kg (704 lbs) of DCE, and 12.8 kg (28.2 lbs.) of TCA. An additional 230 kg (500 lbs) of contaminants consisting of about 200 kg (430 lbs) of TCE, 27 kg (60 lbs) of DCE, and 3.4 kg (7.4 lbs.) of TCA were removed from the aquifer by the source containment well. Thus, the total mass of contaminants removed from the aquifer by both wells between the start of the off-site containment well operation on December 1998 and the end of 2009 was about 5,880 kg (12,960 lbs) consisting of 5,510 kg (12,410 lbs) of TCE, 350 kg (760 lbs) of DCE, and 16 kg (36 lbs) of TCA. This removed mass represented about 75 percent of the contaminant mass currently estimated to have been present in the aquifer prior to the operation of the off-site containment well.

The operation of the soil vapor extraction systems at vapor recovery well VR-1 in 1999 and 2000 had a measurable impact on soil-gas concentrations at the site. The 1999 SVE operations had reduced TCE concentrations in soil gas below 10 ppmv at all but one of the monitored locations. Soil-gas was not monitored during the 2000 and 2001 operation of the 400-cfm system. The system was shut down on June 15, 2001; and performance monitoring was conducted near the end of 2001, three months after the shut-down. The results of this monitoring indicated that soil gas concentrations at all monitoring locations were considerably below the 10 ppmv termination criterion for the system, and the system was dismantled in May 2002.

The remedial systems were operated with only minor difficulties during 1999 through 2009. In 1999, the metering pump adding anti-scaling chemicals to the influent to the off-site air-stripper was not operating correctly. This problem was solved in December 1999 by replacing the pump. Also, chromium concentrations in the influent to, and hence in the effluent from, the air stripper increased from 20 $\mu\text{g/L}$ at system start-up to 50 $\mu\text{g/L}$ by May 1999, and fluctuated near this level, which is the discharge permit limit for the infiltration gallery, throughout the remainder of 1999 and during 2000. To solve this problem, a chromium reduction process was added to the treatment system on December 15, 2000; the process was discontinued on November 1, 2001, after chromium concentrations declined to levels that no longer required treatment. In 2006, the discharge rate of the source containment well began declining during the latter half of the year; it was thought that this was due to the inefficiency of its pump and a new pump was installed in 2007. Further testing conducted when the new pump did not improve the flow rate indicated that the pipeline between the well and the air-stripper

building was clogged with iron and manganese deposits; the pipeline was cleaned with acid in June 2007 to restore the capacity of the well.

Another issue of concern that developed during these years was the continuing presence of contaminants in the DFZ monitoring well MW-71. During 2001, an investigation was conducted on the well and the well was plugged. Based on the results of the investigation, a replacement well, MW-71R located about 30 ft south of the original well, was installed in February 2002. Samples collected from the replacement well between its installation and the end of 2003 indicated the continuing presence of contaminants in the Deep Flow Zone (TCE concentrations of 130 to 210 µg/L). In late 2003, USEPA/NMED and Sparton began negotiating potential approaches for addressing this problem; these negotiations led to the agreement in October 2004 of installing a DFZ monitoring/stand-by extraction well near CW-1, with the understanding that the decision to use this well as a monitoring or extraction well was to be based on whether the well is clean or contaminated. A Work Plan for the installation, testing, monitoring, and/or operation of this DFZ well was submitted to USEPA/NMED on December 6, 2004 and approved by USEPA/NMED on January 6, 2005. Difficulties in obtaining an easement agreement from the City of Albuquerque to provide access through a City owned park for moving a drilling rig to the proposed well location delayed the installation of the well until the beginning of 2006. The well was installed in February 2006, and the first samples from the well were obtained during its testing in April 2006. The analyses of these samples indicated that the well did not contain any site-related contaminants. Details on the installation, testing and sampling of the well were included in a letter-report⁶ presented to USEPA/NMED in June 2006, and the results of the analysis of aquifer test data from the well were presented in Appendix E of the 2007 Annual Report (SSP&A, 2008). Based on the sampling results, the well was designated as monitoring well MW-79, and added to the Monitoring Plan under a semi-annual sampling schedule. Water-quality data collected from MW-79 and MW-71R until the end of 2009 indicated that MW-79 continued to remain free of contaminants, and that VOC concentrations in MW-71R began declining in 2005, from about 185 µg/L in November 2004 to about 55 µg/L in November 2008, and remained at those levels throughout 2009; the November 2009 concentrations in the well were 57 µg/L for TCE, 2.2 µg/L for DCE and <1.0 µg/L for TCA.

Six water table (UFZ) monitoring wells (MW-14, MW-15, MW-28, MW-37, MW-50, and MW-52) that became dry due to declining water levels were plugged during 2002 and 2003; three of these wells were replaced by wells with longer screens (MW-14R, MW-37R, and MW-52R) spanning both the UFZ and ULFZ. Three other water table monitoring wells that became dry during 2004 through 2006 (PW-1, MW-35, and MW-36) were plugged and abandoned in 2007. Well MW-53, which was dry in November 2005 and again in November 2007 and 2008, was deepened in December 2008; the well is now referred to as MW-53D. Well MW-33, which had been dry since 2006, was plugged and abandoned in July 2009.

⁶ Letter dated June 2, 2006 to USEPA and NMED representatives from Stavros S. Papadopoulos of SSP&A and Gary L. Richardson of Metric with subject "Sparton Technology, Inc. Former Coors Road Plant Remedial Program - Transmittal of Data from the Installation, Testing, and Sampling of a new DFZ Well."

In their comments on the 2003-2007 Annual Reports⁷ USEPA and NMED requested that one or more wells or well clusters be installed “west to-northwest of MW-65 and OB-2.” After negotiations between agency and Sparton representatives, Sparton agreed on March 30, 2009 to install one “sentinel” well (monitoring well MW-80) downgradient of the existing plume. Negotiations on the location and screened interval of this well continued throughout the remainder of 2009.⁸

Other minor problems during the past years of operation included the occasional shutdown of the containment systems due to power failures, failures of the monitoring or paging systems, and failures of the discharge pumps or air-stripper blower motors. Appropriate measures were taken to address these problems.

⁷ Letter dated December 30, 2008 from Chuck Hendrickson of USEPA, Region 6 and John Kielsing of NMED to Tony Hurst of Hurst Engineering Services, Re: 2003-2007 Annual Reports, Sparton Technology, Inc., Former Coors Road Plant, Sparton Technology, Inc., Consent Decree, Civil Action No. CIV 97 0206 LH/JHG, EPA ID No. NMD083212332, with enclosure on “EPA/NMED Comments on Sparton, Inc., Annual Reports for 2003-2007.”

⁸ Agreement on the location, and completion of such a sentinel well was reached in early 2010 (see SSP&A and Metric, 2010), and the well was installed in July-August 2010.

Section 3

System Operations - 2010

3.1 Monitoring Well System

During 2010, water levels were measured in and samples were collected from all monitoring wells that were not dry and had sufficient water during the measurement or sampling event. Water levels were measured quarterly and samples were collected from each well at the frequency specified either in the Monitoring Plan, or the Discharge Permit.

3.1.1 Upper Flow Zone

The continuing water-level declines in the Albuquerque area continued to affect shallow monitoring wells (UFZ wells) at the Site. Water levels could not be measured in monitoring wells MW-13, MW-48, MW-57, and MW-61 during all four of the scheduled quarterly water-level measurement events in 2010 because the wells were dry during these events. Because dry conditions in wells MW-13, MW-48, and MW-57 persisted for several years, the 2009 Annual Report (SSP&A, 2010) recommended that wells MW-13 and MW-48 be plugged and abandoned and that well MW-57 deepened. The 2009 Annual Report was approved on September 28, 2010⁹ and the plugging and abandonment of wells MW-13 and MW-48 and the deepening of MW-57 have been scheduled for the summer of 2011. In addition to these three wells, wells MW-47, MW-58, and MW-61, which are scheduled for annual sampling, could not be sampled in November 2010 because they were either dry or did not have sufficient water to be sampled. Water levels in wells MW-07 and MW-09 were close to being at, or below, the bottom of the well screens when the wells were sampled for annual analysis in the fourth quarter of 2010.

3.1.2 Deeper Flow Zones

A new ULFZ/LLFZ monitoring well, well MW-80, was installed in July-August, 2010 northwest of the leading edge of the off-site plume and beyond the capture zone of the off-site containment well (see Figure 2.3 for well location). After installation and development, the well was sampled on August 18, 2010 and found to be free of any site-related contaminants. Based on the results of this sampling event, placed on a quarterly schedule for water-level measurements and sampling. There were no problems associated with the measurement of the water levels or with the sampling of this or of any other monitoring wells completed in the ULFZ, LLFZ, or the DFZ.

3.2 Containment Systems

3.2.1 Off-Site Containment System

The Off-Site Containment System operated for about 8179 hours, or 93.4 percent of the 8,760 hours available during 2010. The system was down for about 581 hours due to 27

⁹ Letter dated September 28, 2010 from John E. Kielling of NMED and Chuck Hendrickson of USEPA to Joseph S. Lerczak of Sparton, Re: 2009 Annual Report Approval, Sparton Technology, Inc., EPA ID No. NMD083212332.

interruptions ranging in duration from 0.17 hour to about 195 hours. A summary of the downtime for the year is presented in Table 3.1 (a). These downtimes consisted of three shutdowns for routine maintenance, one shutdown for well pump replacement, six shutdowns due to power failure, six shutdowns for sump pump adjustments, one shutdown for sump pump replacement, and ten shutdowns for float switch failure.

3.2.2 Source Containment System

The Source Containment System operated for about 8590 hours, or 98.1 percent of the 8,760 hours available during 2010. The system was down for about 170 hours due to 7 interruptions ranging in duration from 0.37 hour to about 67.5 hours. A summary of the downtime for the year is presented on Table 3.1 (b). These downtimes consisted of one shutdown for valve adjustment, two shutdowns for system repairs, three shutdowns due power failure, and one shutdown for a float switch error.

The rapid infiltration ponds performed well during 2010. Ponds 1 and 4 were used during January, March, May, July, September, and November. Ponds 2 and 3 were used during February, April, June, August, October, and December. The amount of water evaporating from the ponds has been estimated to be about 1 percent of the discharged water, that is, about 0.5 gpm.

3.3 Problems and Responses

Most of the downtimes that occurred in 2010 were due to float switch errors and repair (10 for the off-site system and 2 for the source system) and power failures (6 for the off-site system and 3 for the source system). The longest shutdown of a containment system during 2010 was that of the off-site system which occurred from October 14 to October 22 to replace the well pump and to make other changes to the system for accommodating the new pumping rate of 300 gpm recommended for this well by Sparton (SSP&A, 2009b) and approved by the agencies;¹⁰ the system returned to operation after 195 hours. After the increase of the pumping rate on November 3, 2010, difficulties were encountered in maintaining a pumping rate of 300 gpm with the new pump, and the pump was replaced again on November 17, 2011; for this replacement, the system was down only for about 5 hours (see Table 3.1).

Another problem has been the reduction in the pumping rate of source containment well CW-2. The design pumping rate of this well is 50 gpm but the average pumping rate of the well during 2010 was 42 gpm. A similar reduction in this well's pumping rate had occurred in the past, and its cause was determined to be back-pressure caused by scale accumulating in the pipeline to the treatment plant; cleaning the pipeline restored the pumping rate. Cleaning of the pipeline to restore again the pumping rate of the well has been scheduled for January 2011.¹¹

¹⁰ See document cited in Footnote 1.

¹¹ The pipeline was cleaned on January 25, 2011; the average pumping rate of CW-2 after the clean-up (February through May 2011) was 55 gpm.

Section 4

Monitoring Results - 2010

The following data were collected in 2010 to evaluate the performance of the operating remedial systems and to meet the requirements of the Consent Decree and of the permits for the site:

- water-level and water-quality data from monitoring wells,
- data on containment well flow rates, and
- data on the quality of the influent to and effluent from the water-treatment systems.

4.1 Monitoring Wells

4.1.1 Water Levels

Water levels during 2010 were measured quarterly, as it has been the case in past years; however, an extra round of water-level measurements was conducted in late December 2010, approximately four weeks after the pumping rate of CW-1 was increased to 300 gpm, to provide data for evaluating the effects of this new pumping rate. During each round of measurements, the depth to water was measured in all monitoring wells that were not dry during the measurement round, the off-site and source containment wells, the two observation wells, the piezometer installed in the infiltration gallery, and the Corrales Main Canal near the southeast corner of the Sparton property; the November and December measurement rounds also included monitoring well MW-80 which was completed in August 2010,. The corresponding elevations of the water levels during each of the five measurement rounds, calculated from these data, are summarized on Table 4.1.

4.1.2 Water Quality

Monitoring wells within and in the vicinity of the plume were sampled at the frequency specified in the Monitoring Plan and the Discharge Permit. The samples were analyzed for VOCs and for total chromium (unfiltered, and occasionally filtered, samples). The results of the analysis of the samples collected from these monitoring wells during all sampling events conducted in 2010, and for all of the analyzed constituents, are presented in Appendix A-1. Data on TCE, DCE, and TCA concentrations in samples collected during the Fourth Quarter (November 2010) are summarized on Table 4.2. Quarterly samples from the infiltration gallery monitoring wells (MW-74, MW-75, and MW-76) and from the infiltration pond monitoring wells (MW17, MW-77, and MW-78) were analyzed for VOCs, total chromium, iron, and manganese, as specified in the Discharge Permit. The results of the analysis of these samples are presented in Appendix A-2; data on TCE, DCE and TCA concentrations in the Fourth Quarter (November 2010) samples from these wells are also included on Table 4.2. For each of the compounds reported on Table 4.2 and in Appendix A, concentrations that exceed the more stringent of its MCL for drinking water or its maximum allowable concentration in groundwater set by NMWQCC are highlighted.

In addition, well MW-80 was sampled on August 18, 2010 after its completion and development; the results of this sampling event are also included in Appendix A-1. Based on the results of this first sampling of the well (non-detect for site-related VOCs), the well was placed on a quarterly schedule for water-level and water-quality monitoring.

4.2 Containment Systems

4.2.1 Flow Rates

The volumes of groundwater pumped by the off-site and source containment wells during 2010 and the corresponding flow rates are summarized on Table 4.3. As shown on this table, a total of about 136.8 million gallons of water, corresponding to a combined flow rate of 260 gpm were pumped by the two containment wells. The volume and average flow rate of each well are discussed further below.

4.2.1.1 Off-Site Containment Well

The volume of the water pumped by the off-site containment well during 2010 was monitored with a totalizer meter that was read at irregular frequencies. The intervals between meter readings ranged from about 1.7 days to about 8.9 days, and averaged about 6.2 days. During each reading of the meter, the instantaneous flow rate of the well was calculated by timing the volume pumped over a specific time interval. The totalizer data collected from these flow meter readings and the calculated instantaneous discharge rate during each reading of the meter are presented in Appendix B-1. Also included in this appendix are the average discharge rate between readings and the total volume pumped between the start of continuous pumping on December 31, 1998, and the time of the measurement, calculated from the totalizer meter readings.

The average monthly discharge rate and the total volume of water pumped from the off-site containment well during each month of 2010, as calculated from the totalizer data, are summarized on Table 4.3. As indicated on this table, approximately 115 million gallons of water, corresponding to an average rate of 218 gpm, were pumped in 2010.

4.2.1.2 Source Containment Well

The volume of the water pumped by the source containment well during 2010 was also monitored with a totalizer meter that was also read at irregular frequencies. The intervals between meter readings ranged from about 0.6 day to about 10.4 days, and averaged 6.4 days. During each reading of the meter, the instantaneous flow rate of the well was calculated by timing the volume pumped over a specific time interval. The totalizer data collected from these flow meter readings and the calculated instantaneous discharge rate during each reading of the meter are presented in Appendix B-2. Also included in this appendix are the average discharge rate between readings and the total volume pumped between the start of continuous pumping on January 3, 2002, and the time of the measurement, calculated from the totalizer meter readings.

The average monthly discharge rate and the total volume of water pumped from the source containment well during each month of 2010, as calculated from the totalizer data, are

summarized on Table 4.3. As indicated on this table, approximately 22 million gallons of water, corresponding to an average rate of 42 gpm, were pumped in 2010.

4.2.2 Influent and Effluent Quality

4.2.2.1 Off-Site Containment System

During 2010, the influent¹² to and effluent from the treatment plant for the off-site containment system was sampled monthly. These monthly samples were analyzed for VOCs, total chromium, iron, and manganese. The results of these influent and effluent sample analyses are presented in Appendix C-1. Concentrations of TCE, DCE, TCA, and total chromium in samples collected during 2010 are summarized on Table 4.4 (a). For each of the compounds shown on Table 4.4 (a), concentrations that exceed the more stringent of its MCL for drinking water or its maximum allowable concentrations in groundwater set by NMWQCC are highlighted. Data on TCE, DCE, and TCA concentrations for the November sample of influent are also included in Table 4.2, as the Fourth Quarter concentrations in CW-1, and were used in the preparation of the plume maps discussed in the next section.

4.2.2.2 Source Containment System

During 2010, the influent to and effluent from the treatment plant for the source containment system was sampled monthly. These monthly samples were analyzed for VOCs, total chromium, iron, and manganese. The results of these influent and effluent sample analyses are presented in Appendix C-2. Concentrations of TCE, DCE, TCA, and total chromium in samples collected during 2010 are summarized on Table 4.4 (b). For each of the compounds shown on Table 4.4 (b), concentrations that exceed the more stringent of its MCL for drinking water or its maximum allowable concentrations in groundwater set by NMWQCC are highlighted. Data on TCE, DCE, and TCA concentrations for the November sample of influent are also included in Table 4.2, as the Fourth Quarter concentrations in CW-2, and were used in the preparation of the plume maps discussed in the next section.

¹² The “discharge from the containment wells” is the “influent” to the treatment systems; therefore, the two terms are used interchangeably in this report.

Section 5

Evaluation of Operations - 2010

The goal of the off-site containment system is to control hydraulically the migration of the plume in the off-site area and, in the long-term, restore the groundwater to beneficial use. The goal of the source containment system is to control hydraulically, within a short distance from the site, any potential source areas that may be continuing to contribute to groundwater contamination at the on-site area. This section presents the results of evaluations based on data collected during 2010 of the performance of the off-site and source containment systems with respect to their above-stated goals.

5.1 Hydraulic Containment

5.1.1 Water Levels and Capture Zones

The water-level elevation data presented in Table 4.1 were used to evaluate the performance of both the off-site and source containment wells with respect to providing hydraulic containment for the plume and potential on-site source areas. Maps of the elevation of the on-site water table and of the water levels in the UFZ/ULFZ and the LLFZ during each round of water-level measurements in 2010 are shown in Figures 5.1 through 5.15. Also shown on these water-level maps are: (1) the limit of the capture zones of the containment wells in the UFZ/ULFZ or the LLFZ, as determined from the configuration of the water levels; and (2) the extent of the TCE plume. The extent of the TCE plume shown in Figures 5.1 through 5.9 is based on previous year's (November 2009) water-quality data from monitoring wells; the extent of this plume is representative of the area that should have been contained between November 2009 and November 2010. The extent of the plume shown on the water-level maps for November and December 2010 (Figures 5.10 through 5.15), however, is based on the November 2010 water-quality data since this extent represents the area to be captured in November and December.

The evaluation of water-level data from the second quarterly round of measurements (Figures 5.4, 5.5, and 5.6) was limited to the on-site area extending west to Irving Boulevard. This round of measurements, conducted on May 17-18, 2010, coincided with a 13.5-hour shutdown of the off-site containment well CW-1 (see Table 3.1); therefore, during this round water levels in all wells were not measured under similar conditions. On-site wells and wells along and to the east of Irving Boulevard (except wells MW-51 and MW-59) were measured on May 17 before the shutdown of CW-1; most of the remaining wells, particularly those that are used for determining the capture zone of CW-1, were measured in the morning of May 18 while CW-1 was still shutdown, and a few (MW-47, MW-51, MW-55, MW-56, MW-59, MW-67, and MW-79) were measured after CW-1 resumed pumping. Because of these changing conditions the data collected during this round cannot be combined to prepare meaningful water-level maps, particularly in the off-site area where the effects of pumping from CW-1 are most significant. An

evaluation of water-level conditions at the on-site area and its vicinity was made, however, using data from wells that were measured prior to the shutdown of CW-1; therefore, the capture zone of only the source containment well is shown in Figures 5.4, 5.5, and 5.6.

As shown in Figures 5.1, 5.4, 5.7, 5.10 and 5.13, the pumping from the source containment well CW-2 has a relatively small effect on the on-site water table contours. Well CW-2 is screened between an elevation of 4,968.5 and 4,918.5 ft MSL. The sand-pack extends about 10 ft above the top of the screen, to an elevation of about 4,978.5 ft MSL. The top of the 4970-foot silt/clay at this location is also at an elevation of about 4,968.5 ft MSL. Most of the water pumped from the well, therefore, comes from the ULFZ and LLFZ underlying the 4970-foot silt/clay unit. The average pumping water level in CW-2 during 2010 was about 4,954.5 ft MSL, 14 ft below the top of the silt/clay unit; thus, the direct contribution of water from the aquifer above the silt/clay unit into the well is by leakage through the sand pack, and is controlled by the elevation of the top of the silt/clay unit at the well location. In preparing the water-table maps for the on-site area, the elevation of the water table at the location of CW-2 was, therefore, assumed to be near the top of the 4970-foot silt/clay, that is, at an elevation of 4,968.5 ft MSL. A similar condition exists at the location of infiltration pond monitoring wells MW-77 and MW-78. These two monitoring wells are equipped with 30-foot screens that span across the silt/clay unit, and thus allow water to flow from the on-site water table into the underlying ULFZ. The effects of this downward flow were also considered in preparing the water table maps.

The on-site water table maps (Figures 5.1, 5.4, 5.7, 5.10 and 5.13) also indicate that the treated groundwater infiltrating from the infiltration ponds has created a water-table mound in the vicinity of the ponds. Comparisons of the water-level data collected before and after the start of the operation of CW-2 and of the infiltration ponds on January 3, 2002 indicate that soon after the start of the source containment system operation water levels rose in response to the infiltrating water in all but seven of the wells completed above the 4970-foot silt/clay unit; the rise in the water level of the affected wells, between November 2001 and November 2002, ranged from 1.4 ft in well MW-22 to more than 8 ft in well MW-27 and averaged about 4.2 ft. After this initial rise, water levels resumed their declining trend due to regional effects, albeit at a smaller rate than the unaffected wells (see for example the hydrographs of wells MW-17 and MW-22 shown in Figure 2.5). The seven unaffected wells (MW-07, MW-09, MW-12, MW-13, MW-23, MW-26 and MW-33) are located near or along the southern limit of the silt/clay unit; water levels in these seven wells were not significantly affected by the infiltrating water, and continued to decline under the regional trends (see for example the hydrograph of well MW-12 in Figure 2.5). In fact, this regional decline caused two of the wells along the southern boundary of the 4970-foot silt/clay (wells MW-13 and MW-33) to go dry in recent years. The lack of a response to the infiltrating water in the wells located along or near the southern boundary of the silt/clay unit suggests the presence of a low permeability barrier that isolates these wells from the effects of the water infiltrating from the ponds.

The capture zones of the off-site containment well shown in Figures 5.1 through 5.3, and 5.7 through 5.12 correspond to average pumping rates of 219 to 229 gpm that prevailed prior to the measurement of the water levels presented in these figures. As indicated by these figures,

these pumping rates were adequate for providing hydraulic containment of the off-site plume. The increase of the containment well pumping rate to about 300 gpm on November 3, 2010 expanded the width of the well's capture zone by about 250 ft and moved the downgradient limit of the capture zone also by about 250 ft (see Figures 5.13, 5.14, and 5.15), providing a greater safety margin to the hydraulic containment of the off-site plume. These figures also indicate that the source containment well CW-2, despite its lower average pumping rate during 2010, continued to contain potential on-site source areas that may still be contributing to groundwater contamination.

Cross-sectional views of the November 2010 water table are shown on the schematic east-west (C-C') and north-south (D-D') cross-sections that are presented in Figure 5.16 (see Figures 5.10 through 5.12 for the location of these cross-sections). The cross-sections also show the water table that prevailed in November 1998, prior to the start of the off-site containment system. Other features shown on these cross-sections are: (1) the 4970-ft silt/clay unit, (2) the 4800-ft clay unit, (3) the screened intervals of the wells through which the cross-sections are passing (the deepest well at cluster locations), (3) the screened intervals of the DFZ wells, (4) the limits of the containment well capture zones, and (5) the pump intake elevation in the containment wells. The divergence of the water table from the ULFZ potentiometric surface in the area underlain by the 4970-foot silt/clay is shown in greater detail, for both the 1998 and the 2010 conditions in Figure 5.17.

The direction of groundwater flow and the hydraulic gradient in the DFZ during each round of the 2010 water-level measurements in the three DFZ wells, MW-67, MW-71R and MW-79, and for the average water level in these wells are shown in Figure 5.18. As shown in this figure, during 2010 the direction of groundwater flow in the DFZ ranged from W 5.8° S in May to W 47.3° N in November, and the hydraulic gradient from 0.00105 in May to 0.00256 in December. The average direction of groundwater flow in the DFZ during 2010 was W 24.8° N with an average hydraulic gradient of 0.00158.

5.1.2 Effects of Containment Well Shutdown on Capture

As discussed in Section 3, the containment systems are occasionally shut down for maintenance and repairs, and sometimes due to power or equipment failures. For example, during 2008 the off-site containment system was shut down for about 53 hours due to a radio communication failure, and in 2007 the source containment system was shut down for more than 5 days to replace the well pump. A longer shutdown of the off-site containment well occurred in October 2010 when the well was shut down for a little over 8 days to replace the pump and make changes to the system for accommodating a higher pumping rate.

In their review of the 2007 Annual Report USEPA/NMED expressed some concern on whether these shutdowns may result in the escape of contaminants beyond the capture zones of these systems. The capture zone for the source containment well lies within the capture zone of the off-site containment well, and its downgradient limit is within the plume area. Any shutdown of this well would cause some contaminants to escape beyond its capture zone, but

these contaminants will remain within the capture zone of the off-site containment well and eventually captured by this well.

Any contaminants that escape beyond the capture zone of the off-site containment well during the shutdown of this well, however, cannot be recovered unless the pumping rate of the well is increased to develop a larger capture zone. Calculations made to evaluate this possibility indicate that it is highly unlikely. Under non-pumping conditions, the hydraulic gradient (see Figures 2.12 and 2.13) near the leading edge of the plume (see Figure 2.15) is about 0.003. The aquifer above the 4800-foot clay has a hydraulic conductivity of 25 ft/d and a porosity of 0.3. Thus, the rate at which groundwater, and hence contaminants, would move under non-pumping conditions is 0.25 ft/d or about 90 ft/yr. Prior to the increase of the pumping rate of the off-site containment well, the downgradient distance between the limit of its capture zone and the leading edge of the plume was at least 250 ft (see for example Figures 5.11 and 5.12); the increase of the pumping rate to 300 gpm increased this distance by at least another 250 ft (see Figures 5.14 and 5.15). Thus, shutdowns of the length that have been experienced in the past, and of even much longer periods, could not cause any contaminants to escape beyond the capture zone of the well. Hydraulic containment of the plume has been, therefore, maintained during any past shutdowns of the off-site containment system, and will continue to be maintained during any future shutdowns of reasonable duration.

5.2 Groundwater Quality in Monitoring Wells

5.2.1 Concentration Trends

Plots showing temporal changes in the concentrations of TCE, DCE, and TCA were prepared for a number of on-site and off-site wells to evaluate long-term water-quality changes at the Sparton site. Plots for on-site wells are shown in Figure 5.19 and plots for off-site wells in Figure 5.20. The concentrations in the on-site wells (Figure 5.19) indicate a general decreasing trend. In fact, the data from wells MW-9 and MW-16, which have the longest record, suggest that this decreasing trend started before 1983. A significant decrease in concentrations occurred in well MW-16 during 1999 through 2001. This well is located near the area where the SVE system was operating during those years, and it is apparent that the SVE operations affected the concentrations in the well. The TCE concentrations in the well have been below 10 µg/L since November 2003; the November 2010 concentration was 5.4 µg/L. Since the termination of the SVE operations in 2001, relatively low concentrations have been observed not only in this well but also in other onsite wells completed above the 4970-foot silt/clay unit; in fact, only six out of the eleven such wells that were sampled in 2010 had TCE concentrations above 5 µg/L. These six wells (MW-07, MW-09, MW-12, MW-16, MW-25, and MW-26) had concentrations of 13 µg/L, 12 µg/L, 15 µg/L, 5.4 µg/L, 13 µg/L, and 18 µg/L, respectively. This indicates that the cleanup of the unsaturated zone beneath the former Sparton plant area by the SVE system, and the flushing provided by the water infiltrating from the infiltration ponds of the source containment system has been very effective in reducing contaminant concentrations in the saturated sediments overlying the 4970-foot silt clay.

As shown in Figure 5.19, the TCE concentrations in on-site well MW-19, which is completed in the ULFZ below the 4970-foot silt/clay unit (see Figure 2.4), were in the several thousand µg/L level when the well was installed in 1986 and remained at that level for a few years before starting to decline. By November 1998, the TCE concentrations in the well had declined to a few µg/L levels. This declining trend reversed in November 2002 when the TCE concentration rose to 23 µg/L, and then to 630 µg/L by November 2003. The TCE concentrations in the well remained at the several hundred µg/L level until November 2008; however, they began declining again after that date, down to a concentration of 61 µg/L by November 2010. A similar pattern is also displayed in the DCE and TCA concentrations in this well, albeit at lower levels. The concentration increases that were observed during the last several years were most probably due to an increase in the downward migration rate of contaminants present within the 4970-foot silt/clay unit that was caused by increased downward leakage rates across this unit; the increase in leakage rates were induced by the drawdowns below the unit caused by the pumping at CW-2 and the simultaneous increases in the water levels above the unit caused by seepage from the infiltration ponds.

The concentration plots of the six off-site monitoring wells shown in Figure 5.20 do not display a consistent trend; while the concentrations have been declining in most wells (see for example wells MW-55, MW-60, and MW-65) there are others where concentrations remain relatively stable (see for example well MW-37/37R) and some where concentrations began to increase after a period of stabilization (see for example MW-56). This is primarily due to changes in groundwater flow patterns that were caused by the operation of the off-site containment system.

The concentrations in well MW-60 continued to be the highest observed in an off-site well, as it has been the case since the beginning of remedial operations. The concentrations of TCE in this well increased from low µg/L levels in 1993 to a high of 11,000 µg/L in November 1999 and then declined to 2,900 µg/L in November 2000. Then, they began increasing again reaching a second peak of 18,000 µg/L in November 2004; since then TCE concentrations in the well have declined to 1,300 µg/L in November 2010. The DCE and TCA concentrations in this well also declined from 830 µg/L and 59 µg/L in November 2004 to 150 µg/L and 4.7 µg/L, respectively, in November 2010. In general, the “rule-of-thumb” is that the presence of a contaminant at concentrations equal to or exceeding 1% of its solubility indicates the potential nearby presence of that contaminant as a free product (Newell and Ross, 1991; Pankow and Cherry, 1996) usually referred to as a non-aqueous phase liquid (NAPL). The solubility of TCE, a dense NAPL or DNAPL, is 1,100,000 µg/L; the concentrations of 11,000 µg/L and of 18,000 µg/L that were observed in MW-60 in November 1999 and 2004, respectively, meet the criteria of this rule-of-thumb. There are several factors, however, that preclude the presence of a DNAPL source near MW-60. First, the well is screened in the upper part of the aquifer and located almost 2,000 feet downgradient from the site; there is no plausible physical mechanism by which TCE could migrate to such a distance from the site as a DNAPL within a thick and fairly homogeneous aquifer. Second, although TCE concentrations above 10,000 µg/L and as high as 59,000 µg/L have been observed in several on-site wells in 1984 (Harding Lawson

Associates, 1985), DNAPL has not been reported for any on-site boring or monitoring well. Finally, the gradual increase in the concentrations between 1993 and 1999, the occurrence of the high concentrations as two separate peaks with relatively lower concentrations in between, and the subsequent decrease in concentrations indicate that the contaminant concentrations in this well represent two slugs of highly contaminated groundwater that migrated from the site rather than a nearby DNAPL source. The migration of slugs of highly contaminated groundwater from the site is consistent with the high TCE concentrations that were observed at the site in 1984. It is of interest to note that Pankow and Cherry (1996, p. 459) state that “[t]he use of a 1% rule-of-thumb in any assessment of the spatial distribution of DNAPL zones must be performed cautiously, particularly in the downgradient direction. For example, the dissolved plume emitted from a very large DNAPL zone may exhibit dissolved concentrations above 1% of saturation for a substantial distance downgradient of the source zone.”

Monitoring well MW-65, whose concentration trends are also shown in Figure 5.20, had low $\mu\text{g/L}$ levels of TCE when first sampled after installation in 1996; TCE, at concentrations up to about 15 $\mu\text{g/L}$, was the only contaminant detected in this well before and at the start of the off-site containment system. The concentrations of TCE in the well declined rapidly after the start of the off-site containment system to “not detected” (at a detection limit of 1 $\mu\text{g/L}$) in August 1999, and remained “not detected” for almost two years. The well became contaminated again in 2001 but, as shown in Figure 5.20, this time the well contained not only TCE but also DCE and TCA with the dominant contaminant being DCE; the concentrations of these contaminants peaked around 2005 or 2006 and they have been declining since then. There are only two other wells, besides MW-65’s post-2001 contamination, where the dominant contaminant is DCE; these are wells MW-62 and MW-52R. A plot of the contaminant concentrations in these two wells is presented in Figure 5.21; the plot for MW-65 is also repeated in this figure to provide for easy comparison. The dominant contaminant in all other wells associated with the Sparton Site is TCE (see for example the concentration plots of all the other wells shown in Figures 5.19 and 5.20). This indicates that the post-2001 contamination of MW-65 and that of MW-62 and MW-52R is due to a separate, DCE-dominated plume, although some mixing with the main plume may be occurring in the vicinity of MW-52R. During 2010, DCE continued to be the dominant contaminant in these three wells with concentrations of 17 $\mu\text{g/L}$, 7.1 $\mu\text{g/L}$, and 2.5 $\mu\text{g/L}$, in MW-52R, MW-65, and MW-62, respectively. Evaluations of the available data, including backward tracking from well MW-65 using water level data collected since 1992,¹³ and review of historical water-quality data from monitoring wells MW-34 and MW-35,¹⁴ which show that these wells were historically free of contaminants, indicate that the source of this separate plume lies somewhere south or southeast of wells MW-62 and MW-34, and that,

¹³ See Attachment 3 to letter dated February 12, 2009 from Charles B. Andrews of SSP&A to Chuck Hendrickson of USEPA Region 6, and John Kielling of NMED, on the subject: Response to EPA/NMED comments on Sparton Technology, Inc., Former Coors Road Plant Remedial Program, 2003-2007 Annual Reports (including 5 attachments), with cc to Susan Widener, James B. Harris, Tony Hurst, and Gary L. Richardson.

¹⁴ Well MW-35 was located along Irving Boulevard, about 500 ft northwest of MW-34; it became dry in 2002 and was plugged and abandoned in 2007.

therefore, this plume does not originate at the Sparton Facility.¹⁵ Well MW-80, which was installed during 2010 to address agency concerns that this separate plume may have migrated beyond the capture zone of the off-site containment well, was free of the contaminants detected in wells MW-52R, MW-62, and MW-65, or of any other site-related contaminants, when it was first sampled on August 18, 2010, and remained free of these contaminants when it was sampled again in November 2010.

Of the three monitoring wells completed in the DFZ, well MW-67 of the MW-48/55/56/67 cluster had been clean since its installation in July 1996, and continued to be free of any contaminants in 2010. The second DFZ well, MW-71R, located about 30 ft south of the MW-60/61 cluster, was installed in February 2002 as a replacement for DFZ well MW-71 which was plugged and abandoned in October 2001 because of persistent contamination.¹⁶ The first sample from MW-71R, obtained in February 2002, had a TCE concentration of 130 µg/L and the well has remained contaminated since then with TCE concentrations reaching a high of 210 µg/L in August 2003; after that, however, TCE concentrations in the well began to decline reaching a low of 51 µg/L in May 2009. During 2010, the TCE concentrations in the well ranged from 54 µg/L in February to 67 µg/L in August; the November 2010 TCE concentration in the well was 64 µg/L. The third DFZ well, MW-79, was installed near the off-site containment well CW-1 in February 2006 as a monitoring/stand-by extraction well to address the contamination detected in MW-71R; the decision on whether the well was to be a monitoring or an extraction well was to be based on the results of the initial sampling of the well. The initial sampling of the well showed the well to be free of site-related contaminants; therefore, the well was designated as a monitoring well, and added to the Monitoring Plan under a semi-annual sampling schedule. Samples collected from the well since then have been free of any site-related contaminants.

The direction of groundwater flow in the DFZ places wells MW-67 and MW-79 downgradient of the Sparton Facility. The lack of any contaminants in these two DFZ wells and the decline of TCE concentrations in well MW-71R indicate that this well is most likely affected by a contaminant slug of limited extent. The water quality in these three DFZ wells will continue to be monitored closely and periodically evaluated to determine if any future action might be necessary.

¹⁵ USEPA and NMED agree that the contaminants detected in MW-65 and MW-62 are due to a separate plume, but they disagree that this plume did not originate at the Sparton facility; the agencies were also concerned that contaminants that belong to this plume or that have not been captured by the off-site containment system, may be present outside the capture zone of the off-site containment well, and they requested the installation of a sentinel well northwest of MW-65 (see document in Footnote 7 and memorandum dated March 24, 2009 from Stavros S. Papadopoulos of SSP&A to Charles Hendrickson of USEPA, Region 6, and John Kieling, Braid Swanson, and Brian Salem of NMED on the subject: Sparton Technology, Inc. Former Coors Road Plant Remedial Program, Minutes of Conference Call between Representatives of Sparton, USEPA and NMED [including 2 attachments], with cc to Richard Langley and Susan Widener of Sparton, James B. Harris of Thompson & Knight, Tony Hurst of Hurst Eng.'g Services, and Gary Richardson of Metric). Sparton agreed to install this well, and the well was installed in July-August 2010.

¹⁶ See 1999 Annual Report (SSP&A, 2001a) for a detailed discussion of the history of well MW-71, and SSP&A and Metric (2002) for actions taken prior to its plugging and abandonment.

5.2.2 Concentration Distribution and Plume Extent

The Fourth Quarter (November) 2010 TCE and DCE data presented in Table 4.2 were used to prepare concentration distribution maps showing conditions near the end of 2010. The horizontal extent of the TCE and DCE plumes and the concentration distribution within these plumes in November 2010, as determined from the monitoring well data, are shown on Figures 5.22 and 5.23, respectively.¹⁷ In preparing these figures, the fact that wells MW-62, MW-65, and MW-52R are affected by a separate plume was taken into consideration. Concentrations of TCA in all monitoring and extraction wells have been below regulatory standards since 2003; in November 2010 only five of the 57 sampled wells contained TCA above the detection limit of 1 µg/L. The highest TCA concentration, 4.7 µg/L, was measured in well MW-60; the concentrations in the other four wells where TCA was detected were less than 3 µg/L (see Table 4.2). Based on the low concentrations of TCA that have been observed since 2003, Sparton proposed in the 2008 Annual Report (SSP&A, 2009a) that evaluations of TCA data be discontinued, unless concentrations increase above regulatory standards; this proposal was approved by both USEPA¹⁸ and NMED¹⁹ in May 2010. A concentration distribution map for TCA or other evaluations of TCA data are not, therefore, included in this 2010 Annual Report; however, TCA concentrations in the off-site containment well are used in calculating mass removal by this well.

5.2.3 Changes in Concentrations

Fifty-six of the 57 wells sampled in November 2010 were also sampled in November 2009. In these 56 wells, the November 2010 TCE concentrations were lower than the November 2009 concentrations in 15 wells, higher in 17 wells, and remained the same in 24 wells (all below the detection limit of 1 µg/L). The largest decrease was in well MW-60 where the concentration of TCE decreased by 900 µg/L, from 2,200 µg/L in 2009 to 1,300 µg/L in 2010; the largest increase in a monitoring well was at MW-72 where the concentration of TCE increased by 260 µg/L, from 500 µg/L in 2009 to 760 µg/L in 2010. The corresponding numbers for DCE were 11 wells with lower, 5 wells with higher, and 40 wells with the same (39 below the detection limit of 1 µg/L) concentrations. The largest decrease and the largest increase in DCE concentrations were also in wells MW-60 and MW-72, respectively; in well MW-60 the concentration of DCE decreased by 80 µg/L, from 230 µg/L in 2009 to 150 µg/L in 2010, and that in MW-72 increased by 31 µg/L, from 89 µg/L in 2009 to 120 µg/L in 2010. The concentrations of TCE and DCE in on-site monitoring well MW-19, which had increased

¹⁷ At well cluster locations, the concentration shown in Figures 5.22 and 5.23 is that for the well with the highest concentration.

¹⁸ E-mail dated May 11, 2010 from Charles Hendrickson of USEPA to Stavros Papadopoulos of SSP&A with cc to Baird Swanson and Brian Salem of NMED on the subject "Re: Extension approval and Comments on 2008 Report," with an attachment titled "Annual Report 2008 draft comments" which included draft comments by C. Hendrickson, dated March 11, 2010.

¹⁹ E-mail dated May 17, 2010 from John Kielsing of NMED to Stavros Papadopoulos of SSP&A with cc to Charles Hendrickson of USEPA, Baird Swanson and Brian Salem of NMED, Joe Lerczak of Sparton, James Harris of Thompson & Knight, Gary Richardson of Metric, and Tony Hurst of Hurst Engineering on the subject "Re: TCA valuation" indicating that NMED agrees to discontinuing TCA evaluations.

significantly in 2003 (see Figure 5.19) due to increased downward leakage through the 4970 ft silt/clay unit after the start of the source containment system, continued to decline during 2010 as they did during 2009; the concentration of TCE in the well went from 110 µg/L in 2009 to 61 µg/L in 2010 and that of DCE from 19 µg/L in 2009 to 9.8 µg/L in 2010.

Changes that occurred between November 1998 (prior to the implementation of the current remedial activities) and November 2010 in the TCE, and DCE concentrations at wells that were sampled during both sampling events are summarized on Table 5.1. Also included on this table are wells MW-72 and MW-73 which were installed in early 1999 and wells MW-77, MW-78, and CW-2, which were installed in late 2001; the listed changes in these wells are between November 2010 and the first available sample from these wells. Of the 52 wells listed on Table 5.1, the TCE concentrations decreased in 31, increased in 6 and remained unchanged in 15 (below detection limits during both sampling events). The corresponding number of wells where DCE concentrations decreased, increased, or remained unchanged are 27, 5, and 20, respectively. Of the 52 wells listed on Table 5.1, 37 are among the wells that were used for defining the November 1998 plume, or the November 2010 plume, or both. Concentration changes in these 37 wells are presented in Figures 5.24, and 5.25 to show the distribution of concentration changes that occurred since the implementation of the off-site and source containment systems. Also shown on these figures is the extent of the plumes in November 1998 and November 2010. Among these 37 wells, TCE concentrations decreased in 27 wells, increased in 4 wells, and remained unchanged in 6 wells (below detection limits during both sampling events); the corresponding number of these wells where DCE concentrations decreased, increased, or remained unchanged are 24, 4, and 9.

The largest decreases in contaminant concentrations since the beginning of the current remedial operations occurred in on-site wells MW-23, MW-25 and MW-26, and in off-site well MW-60. Concentrations of TCE in on-site wells MW-23, MW-25, and MW-26 decreased by 6,197, 5,587, and 6,482 µg/L, respectively, from levels that were in the 5,500-6,500 µg/L range in 1998 to levels of less than 20 µg/L 2010; DCE concentrations in these three wells decreased by 400, 73, and 590 µg/L, to "not detected" (ND) since 2007 (since 2004 in MW-26). The concentration of TCE in on-site well MW-73, which was installed in early 1999, decreased by 3,986 µg/L, from 4,000 µg/L when it was first sampled on March 5, 1999 to 14 µg/L in November 2010; the DCE concentration in this well decreased by 518 µg/L, from 520 µg/L at its first sampling to less than 2 µg/L in November 2010. At off-site well MW-60, TCE concentrations decreased by 6,400 µg/L, from 7,700 µg/L in 1998 to 1,300 µg/L in November 2010; DCE concentrations in the well decreased by 200 µg/L from 350 µg/L in 1998 to 150 µg/L in 2010. Another off-site well with significant decreases in concentration is well MW-46; TCE concentrations in this well decreased by 1985 µg/L (from 2,200 µg/L to 215 µg/L) and DCE concentration by 97 µg/L (from 130 µg/L to 33 µg/L).

Of the six wells where the current (2010) TCE and DCE concentrations are larger than those in 1998, the largest increases occurred in the off-site containment well CW-1 (490 µg/L, and 62 µg/L, respectively), and on-site ULFZ well MW-19 (57 µg/L and 10 µg/L, respectively).

The concentration increases cited above for the off-site containment well CW-1 are based on the pre-operation concentrations of TCE and DCE in this well (140 µg/L and 2.9 µg/L, respectively). The concentration of TCE in the water pumped from this well increased rapidly after the start of its operation to levels in the 1,000-1,500 µg/L range, and remained at those levels for many years. Concentrations in this well started declining in 2005 [see Figure 6.8 (a)], but they are still higher than 500 µg/L; during 2010, TCE concentrations in the well ranged from 630 µg/L to 840 µg/L, and averaged about 700 µg/L. The persistence of high concentrations in the water pumped from the well, and the concentrations detected at well MW--60 indicate that areas of high concentration were present upgradient from both of these wells. Most of the water in these upgradient areas, however, has been already captured and pumped out by the off-site containment well (see Figure 5.29), and concentrations both in CW-1 and MW-60 are expected to continue to decline.

5.3 Containment Systems

5.3.1 Flow Rates

A total of about 137 million gallons of water, corresponding to an average pumping rate of about 260 gpm, were pumped during 2010 from the off-site and source containment wells (see Table 4.3). The volume of water pumped during each year of the operation of the containment wells is summarized on Table 5.2. As shown on this table, the total volume pumped from both wells since the beginning of remedial pumping in December 1998 is about 1.61 billion gallons, and corresponds to an average rate of 254 gpm over the 12 years of operation. This volume represents approximately 142 percent of the initial plume pore volume reported in Subsection 2.6.1.3 of this report. The volume pumped from each well and the average flow rates are discussed below.

5.3.1.1 Off-Site Containment Well

The volume of water pumped from the off-site containment well during each month of 2010 is shown on Table 4.3; a plot of the monthly production is presented in Figure 5.26. Based on the total volume of water pumped during the year (approximately 115 million gallons), the average discharge rate for the year was 218 gpm. Due to downtimes (see Table 3.1), the well was operated 93.4 percent of the time available during the year, thus the average discharge rate of the well during its operating hours was about 233 gpm. Note, however, that the discharge rate of this well was increased on November 3, 2010. Prior to this increase, the average discharge rate of the well was 207 gpm corresponding to a discharge rate of 223 gpm during operating hours; after the increase, the average discharge rate was 274 gpm corresponding to a rate of 284 gpm during operating hours.²⁰

²⁰ The average pumping rate during the operating hours between November 3 and the end of the year was lower than expected due to difficulties encountered in maintaining the pumping rate at about 300 gpm with the pump that was installed during October 14-22, 2010 (see Section 3.3); the pump was replaced with a higher capacity pump on November 17, 2010 and the average rate after that was 296 gpm.

The volume of water pumped during each year of the operation of the well is summarized on Table 5.2. As shown on this table, the off-site containment well pumped a total of about 1.38 billion gallons of water from the aquifer since the beginning of its operation in December 1998. This represents approximately 122 percent of the initial plume pore volume reported in Subsection 2.6.1.3 of this report. A cumulative plot of the volume of water pumped from the off-site containment well is presented in Figure 5.27.

5.3.1.2 Source Containment Well

The volume of water pumped from the source containment well during each month of 2010 is shown on Table 4.3; a plot of the monthly production is presented in Figure 5.26. Based on the total volume of water pumped during the year (approximately 22 million gallons), the average discharge rate for the year was 42 gpm. The well was operated 98.1 percent of the time available during the year, thus the average discharge rate of the well during its operating hours was 43 gpm. These average pumping rates are lower than the design pumping rate of 50 gpm for this well and appear to be due to back-pressure on the pump caused by scale accumulation in the pipeline taking the pumped water to the treatment plant. Cleaning of the pipeline to restore again the pumping rate of the well was scheduled for January 2011.²¹

The volume of water pumped during each year of the operation of the well is summarized on Table 5.2. As shown on this table, the source containment well pumped a total of about 224 million gallons of water from the aquifer since the beginning of its operation on January 3, 2002. This represents approximately 20 percent of the initial plume pore volume reported in Subsection 2.6.1.3 of this report. A cumulative plot of the volume of water pumped from the source containment well is presented in Figure 5.27. Also shown in Figure 5.27 is a cumulative plot of the total volume of water pumped by both containment wells.

5.3.2 Influent and Effluent Quality

5.3.2.1 Off-Site Containment System

The concentrations of TCE, DCE, TCA, and total chromium in the influent to and effluent from the off-site air stripper during 2010, as determined from samples collected at the beginning of each month, are presented on Table 4.4 (a). Plots of the TCE, DCE, and total chromium concentrations in the influent are presented in Figure 5.28.

The concentrations of TCE in the influent during 2010 ranged from lows of 630 µg/L in the January, August, September, and November samples to a high of 840 µg/L in the May sample. The average concentration for the year was about 700 µg/L; this average concentration was 170 µg/L lower than the average concentration during 2009 (870 µg/L). The lowest (55 µg/L) and highest (73 µg/L) concentrations of DCE were detected in the December and April samples, respectively; the average concentration for the year was about 66 µg/L. Concentrations of TCA in the influent fluctuated within a relatively narrow range (1.9 µg/L to 2.5 µg/L) and

²¹ As stated in Footnote 11, the pipeline was cleaned on January 25, 2011, and the pumping rate since then averaged about 55 gpm.

averaged about 2.2 µg/L. Throughout the year, total chromium concentrations in the influent were below the 50 µg/L maximum allowable concentration in groundwater set by NMWQCC and averaged about 15 µg/L.

The concentrations of TCE, DCE, and TCA in the air stripper effluent were below the detection limit of 1 µg/L throughout 2010. Total chromium concentrations in the effluent were essentially the same as those in the influent.

5.3.2.2 Source Containment System

The 2010 concentrations of TCE, DCE, TCA, and total chromium in the influent to and effluent from air stripper for the source containment system, as also determined from samples collected at the beginning of each month, are presented on Table 4.4 (b). Plots of the TCE, DCE, and total chromium concentrations in the influent are presented in Figure 5.28.

The concentrations of TCE in the influent during 2010 ranged from 44 µg/L in September and November to 69 µg/L in July, and averaged about 51 µg/L. This average concentration was 13 µg/L lower than the average concentration during 2009 (64 µg/L). The concentrations of DCE fluctuated within a relatively narrow range during the year (5.0 µg/L to 11 µg/L) and averaged about 6.8 µg/L. The concentrations of TCA in the influent were below the detection limit of 1 µg/L throughout the year, and total chromium concentrations were below the 50 µg/L maximum allowable concentration in groundwater set by NMWQCC;²² the average total chromium concentration was about 37 µg/L.

The concentrations of TCE, DCE, and TCA in the air stripper effluent were below detection limits throughout 2010, and chromium concentrations were at about the same level as those in the influent, except for the January 2010 sample that had a significantly lower concentration than the influent; this was also the case for the January 2011 sample.²³

5.3.3 Origin of the Pumped Water

The groundwater pumped from the off-site and the source containment wells is water that was originally (prior to the start of pumping) in storage around each well. The areal extent of the volume of the aquifer within which the water pumped during a particular period was originally

²² The total chromium concentration in the influent sample for January 2011 was 78 µg/L [see Table 4.4(b)]; this may suggest that chromium concentrations in the influent were above the 50 µg/L limit near the end of 2010. The sample also had high iron and manganese concentrations (see Appendix C-2). The reduced pumping rate of CW-2 during 2010 indicates that scale has again accumulated in the pipeline between the well and the treatment plant. The higher concentrations of chromium and of iron and manganese in the January 2011 sample are therefore, most probably due to a dislodged piece of scale from the pipeline rather than an increase in the concentration of these constituents in the pumped water. In fact, after the pipeline was cleaned in mid-January 2011 chromium concentrations in influent samples for February through June 2011 were all about 30 µg/L. This is also consistent with the lower chromium concentration in the corresponding effluent sample (43 µg/L); the samples are unfiltered, and some of the particulates in the influent settled in the air stripper resulting in lower concentrations in the effluent sample.

²³ See Footnote 22.

stored is referred to as the “area of origin” of the water pumped during that period. Particle tracking analysis (see Section 6.1.3) with the calibrated model of the site was used to determine the areas of origin of the water pumped from the off-site containment well during the last twelve years and from the source containment well during the last nine years. The results of this analysis are presented in Figure 5.29. The areas from where the water pumped during different periods originated are shown in Figure 5.29 (a); the schematic cross-section of Figure 5.29 (b) shows the vertical extent of these areas of origin. The areas of origin of the water pumped by each of the two containment wells are discussed below.

5.3.3.1 Off-Site Containment Well

For the off-site containment well, which is fully penetrating the aquifer above the 4,800-foot clay, the area of origin of the water pumped during the first few years of its operation (1999-2001) is an almost circular area around the well, with the well off-centered on the down-gradient side of the area [Figure 5.29 (a)]. The areas of origin corresponding to subsequent years of operation form rings around this first area, which become more and more elliptical and more and more skewed towards the upgradient side (southeast) of the well. The shape and location of the areas of origin with respect to the containment well are controlled by the capture zone of the well. Since the capture zone is a limiting flow line, the areas of origin become narrower as they approach the downgradient (northwestern) limit of the capture zone and the stagnation point of the flow field. The area of origin of the water pumped until the end of 2009 had already reached this limit of the capture zone; therefore, very little of the water pumped, during 2010 originated from this area; however, the increased pumping rate of CW-1 is pushing the limit of the capture zone farther to the northwest (see Figures 5.14 and 5.15). Thus, some of the water to be pumped in future years will originate from the area between the pre- and post-increase limit of the capture zone. Note also that the area of origin of water pumped until 2009 and that of the water pumped during 2010 have a tail at their eastern extent, where these areas meet the capture zone of well CW-2. Since water within the capture zone of CW-2 is captured by CW-2, the water pumped by CW-1 has to come outside this area; in 2010, this water came from the area north of the CW-2 capture zone and the aquifer beneath the 4970-foot silt/clay unit with some downward leakage through this unit. As pumping continues, the area of origin of the water pumped by CW-1 may also expand to the south of the CW-2 capture zone, surrounding the limit of this zone.

Since the well is fully penetrating, the areas of origin of the water pumped by this well remain essentially the same at different depths [see Figure 5.29 (b)], except that water derived from vertical drainage due to the decline of the water table reduces the areal extent of the area of origin in the upper horizons of the aquifer; the effect of vertical drainage was more pronounced during the early years of operation when the rapid decline of the water table in response to the start of pumping contributed a greater percentage of the pumped water than in later years.

5.3.3.2 Source Containment Well

Hydrogeologic conditions in the vicinity of the source containment well are different than in the vicinity of the off-site containment well because of the presence of the 4970-foot silt/clay unit, the presence of different deposits in the upper part of the aquifer between the Site and the Rio Grande (the Upper Sand Unit and the Recent Rio Grande deposits, as shown in Figure 2.2

and Figure 6.1), and the partial penetration of the aquifer by the source containment well. The screened interval of the well extends about 40 ft into the aquifer below the 4970-foot silt/clay unit; groundwater flow towards this screened interval is, therefore, influenced by downward leakage through the silt/clay unit and from the Upper Sand Unit, by flow from the Recent Rio Grande deposits, and by upward leakage from horizons of the aquifer below the screened interval. Because of these influences the areas of origin of the water pumped by this well are more elongated towards the east-southeast [Figure 5.29 (a)]. Note that the area of origin of the water pumped by this well by the end of 2009 had already reached the limit of the capture zone for this well not only on the downgradient side but also along the northeastern and southwestern flanks in the vicinity of the Sparton site; therefore, the area of origin of water pumped during 2010 lies along the eastern parts of the northeastern and southwestern flanks of the capture zone and along the Corrales Main Canal. The areas of origin of water to be pumped by CW-2 in future years are not expected to be significantly different as recharge to the current area of origin, which includes downward leakage through the 4970-foot silt/clay unit and seepage from the canal and the Rio Grande, is approximately equal to the pump rate of CW-2.²⁴

5.3.4 Contaminant Mass Removal

A total of about 340 kg (750 lbs) of contaminants, consisting of about 310 kg (680 lbs) of TCE, 29 kg (64 lbs) of DCE, and 1.0 kg (2.1 lbs) of TCA, were removed by the two containment wells during 2010 [see Table 5.3 (a)]. A plot of the TCE, DCE and total mass removed by the two containment wells during each month of 2010 is presented in Figure 5.30. The total mass of contaminants removed by the two containment wells during each year of their operation is summarized on Table 5.4 (a), and a plot of the cumulative TCE, DCE, and total mass removed by the wells is presented in Figure 5.31. As shown on Table 5.4 (a), the total mass removed by the containment wells, since the beginning of the current remedial operations in December 1998, is about 6,210 kg (13,710 lbs), consisting of about 5,820 kg (12,820 lbs) of TCE, 376 kg (830 lbs) of DCE, and 17 kg (38 lbs) of TCA. This represents about 79 percent of the total dissolved contaminant mass currently estimated to have been present in the aquifer prior to the testing and operation of the off-site containment system (see Section 2.6.1.4). The mass removal rates by each well are discussed below.

5.3.4.1 Off-Site Containment Well

The monthly mass removal rates of TCE, DCE, and TCA by the off-site containment well during the 2010 were estimated using the monthly discharge volumes presented on Table 4.3 and the concentration of these compounds shown on Table 4.4 (a). These monthly removal rates are summarized on Table 5.3 (b); plots of the monthly TCE and DCE removal rates are presented in Figure 5.30. As shown on Table 5.3 (b), about 335 kg (740 lbs) of contaminants, consisting of

²⁴ In the numerical model, which is used to determine the areas of origin of the containment wells, the Rio Grande is simulated as a river (constant head) boundary that extends to the levees of the river (see Figure 6.1). Near the eastern edge of area of origin for water pumped by CW-2, the river levee runs parallel to the Corrales Main Canal; therefore, in the model, the area of origin already extends to the river and derives any differences between the pumping rate and leakage from seepage from the river. Thus, the modeled areas of origin are not expected to expand farther to the east; in reality, we can assume that the area of origin has already reached the western bank of the river, or that it will reach it very soon.

about 305 kg (675 lbs) of TCE, 29 kg (63 lbs) of DCE, and 1.0 kg (2.1 lbs) of TCA were removed by the off-site containment well during 2010.

The mass of contaminants removed by this well during each year of its operation is summarized on Table 5.4 (b), and a plot showing the cumulative TCE, DCE, and total mass removal by the off-site containment well is presented in Figure 5.31. As shown on Table 5.4(b), by the end of 2010 the off-site containment well had removed a total of approximately 5,980 kg (13,200 lbs) of contaminants, consisting of approximately 5,620 kg (12,380 lbs) of TCE, 348 kg (768 lbs) of DCE, and 14 kg (30 lbs) of TCA. This represents about 76 percent of the total dissolved contaminant mass currently estimated to have been present in the aquifer prior to the testing and operation of the off-site containment system (see Section 2.6.1.4).

5.3.4.2 Source Containment Well

The monthly mass removal rates of TCE and DCE by the source containment well during the 2010 were estimated using the monthly discharge volumes presented on Table 4.3 and the concentration of these compounds shown on Table 4.4 (b). These monthly removal rates are summarized on Table 5.3 (c) and plotted in Figure 5.30. As shown on Table 5.3 (c), about 4.9 kg (11 lbs) of contaminants, consisting of about 4.3 kg (9.5 lbs) of TCE and 0.57 kg (1.3 lbs) of DCE were removed by the source containment well during 2010.

The mass of contaminants removed by this well during each year of its operation is summarized on Table 5.4 (c), and a plot showing the cumulative TCE, DCE, and total mass removal by the source containment well since the beginning of its operation on January 3, 2002 is presented in Figure 5.31. As shown on Table 5.4 (c) and Figure 5.31, the total mass of contaminants removed by the well by the end of 2010 was about 230 kg (510 lbs), consisting of 200 kg (440 lbs) of TCE, 28 kg (61 lbs) of DCE, and 3.4 kg (7.4 lbs) of TCA. This represents about 3 percent of the total dissolved contaminant mass currently estimated to have been present in the aquifer prior to the testing and operation of the off-site containment system (see Section 2.6.1.4).

5.4 Site Permits

5.4.1 Off-Site Containment System

The infiltration gallery associated with the off-site containment system is operated under the Discharge Permit (State of New Mexico Groundwater Discharge Permit DP-1184). This permit requires monthly sampling of the treatment system effluent, and the quarterly sampling of the infiltration gallery monitoring wells MW-74, MW-75 and MW-76. The samples are analyzed for TCE, DCE, TCA, chromium, iron, and manganese. The concentrations of these constituents must not exceed the maximum allowable concentrations for groundwater set by NMWQCC. As required by the current Discharge Permit, the analysis results of all samples collected during 2010 were reported to the NMED Groundwater Bureau in the 2010 Annual

Monitoring Report for the permit submitted to the Bureau on February 22, 2011.²⁵ The sampling results met the permit requirements throughout the year.

The air stripper associated with the off-site containment system is operated under Air Quality Source Registration No. NM/001/00462/967, issued by the Air Quality Services Section, Air Pollution Control Division, Environmental Health Department, City of Albuquerque. This registration limits the hourly and annual VOC mass emitted by the stripper to 0.32 lbs/hr and 1.37 tons/yr. The emissions from the air stripper were calculated in June 1999, after the stripper had been put into continuous operation; the results of this calculation, which were reported to the agency that issued the registration, were in full compliance with the specified emission limits. Under the terms of the registration, further monitoring and/or reporting of the emissions from the air stripper was not required, and has not been carried out since that time. Based on the VOC mass removed by the off-site containment well during 2010 (335 kg or 740 lbs), and assuming that 100% of this mass was transferred to the air-stripped stack, the VOC mass emitted during the year averaged 0.08 lbs/hr or 0.37 tons/yr, well within the specified emission limits.

No violation notices were received during 2010 for activities associated with the operation of the off-site containment system.

5.4.2 Source Containment System

The rapid infiltration ponds associated with the source containment system are also operated under State of New Mexico Groundwater Discharge Permit DP-1184, and are subject to the above-stated requirements of this permit. The monitoring wells for this system are MW-17, MW-77 and MW-78; the data collected from these wells met the requirements of the Groundwater Discharge Permit throughout 2010, and were also included in the 2010 Annual Monitoring Report for the permit.¹⁶

The air stripper associated with the source containment system is operated under Albuquerque/Bernalillo County Authority-to-Construct Permit No. 1203. This permit specifies emission limits for total VOCs, TCE, DCE, and TCA. Emissions from the air stripper are calculated annually and reported to the Albuquerque Environmental Health Department, Air Quality Division by March 15 every year as required by the permit. The calculated emissions for 2010, 0.0015 lbs/hr or 0.0066 tons/yr, which were reported to the Albuquerque Air Quality Division on March 4, 2011,²⁶ met the requirements of Permit No. 1203 throughout 2010.

No violation notices were received during 2010 for activities associated with operation of the source containment system.

²⁵ Letter dated February 22, 2011 to Ms Naomi Davidson of the NMED Groundwater Bureau from Stavros S. Papadopoulos of SSP&A and Gary L. Richardson of Metric on the subject: 2010 Annual Monitoring Report for Discharge Permit DP-1184.

²⁶ Letter dated March 4, 2010 to Ms. Regan Eyerman of the Albuquerque Environmental Health Department, Air Quality Division from Stavros S. Papadopoulos of SSP&A and Gary L. Richardson of Metric on the subject: Authority-to-Construct Permit#1203 – 2010 Annual Report on Air Emissions.

5.5 Contacts

On June 28, 2010, Ms. Naomi Davidson of the NMED Groundwater Bureau visited the site and was given a tour of the facilities associated with the site.

Under the terms of the Consent Decree,²⁷ Sparton is required to prepare an annual Fact Sheet summarizing the status of the remedial actions, and after approval by USEPA/NMED, distribute this Fact Sheet to property owners located above the plume and adjacent to the off-site treatment plant water discharge pipeline. Fact Sheets reporting on remedial activities during 1999 through 2006 were prepared by Sparton, approved by the regulatory agencies, and distributed to the property owners. After the approval of the 2007 and 2008 Annual Reports in July 2010,²⁸ and of the 2009 Annual Report in September 2010,²⁹ Sparton prepared a combined 2007 through 2009 Fact Sheet and submitted it to the USEPA/NMED for approval on October 21, 2010. The agencies approved this Fact Sheet on November 15, 2010, and it was distributed to the property owners located above the plume and adjacent to the off-site treatment plant water discharge pipeline during the second half of November 2010.

Section 6

Groundwater Flow and Transport Model

This section describes a numerical groundwater flow and contaminant transport model of the aquifer system underlying the Sparton site and its vicinity that has been used to evaluate water levels and TCE concentrations. This model was developed following the general outline described in Task 3 of the “Work Plan for the Assessment of Aquifer Restoration” (SSP&A, 2000b), which is incorporated as Attachment D in the Consent Decree. The development of the current version of the model is described in detail in the 2008 Annual Report (SSP&A, 2009a). The initial version of the model was described in the 1999 Annual Report (SSP&A, 2001) and the model has been updated and recalibrated several times since then as described in the 2008 Annual Report (SSP&A, 2009a) and in the 2009 report on the Evaluation of Alternative Systems for Aquifer Restoration (SSP&A, 2009b), hereafter “Alternatives Report.” The groundwater flow model is based on MODFLOW-2000 (Harbaugh and others, 2000). The flow model is coupled with the solute transport simulation code MT3D (Zheng, 2008; Zheng and SSP&A, 1999) for the simulation of the movement of constituents of concern in the aquifer underlying the site, and the particle tracking codes PATH3D (Zheng, 1991) and MODPATH (Pollock, 1994; 2008) for the calculation of capture zones and of areas of origin, respectively. The models have been used to simulate groundwater levels and TCE concentrations in the aquifer from start-up of the off-site containment well in December 1998 through December 2011.

6.1 Groundwater Flow Model

6.1.1 Structure of Model

The model area and model grid are presented in Figure 6.1. The overall model dimensions are 15,000 ft by 9,500 ft. The model consists of 88 rows and 133 columns. The central part of the model covers a finely gridded area of 4,900 ft by 2,800 ft which includes the Site and the off-site plume; the grid spacing in this area is uniform at 50 ft. Outward from this central area, the grid spacing is gradually increased to as much as 1,000 feet at the limits of the model domain. The column axis of the model grid is aligned with the approximate direction of regional groundwater flow (W 25° N).

The model consists of 15 layers. The vertical discretization used in the model is shown in Figure 6.2. Layers 1 through 11 correspond to the surficial aquifer. Layer 1 is 15 ft thick, layer 2 is 5 ft thick, layers 3 through 7 are 10 ft thick, layers 8 and 9 are 20 ft thick, and layers 10 and 11 are 40 ft thick. Layer 12 is a 4-foot-thick unit that represents the 4800-foot clay unit. Layer 13 represents the 76-foot thick deep flow zone, layer 14 represents the 15-foot thick 4705-foot clay unit, and layer 15 represents the upper 165 ft of the deeper aquifer units.³⁰ The vertical discretization was selected to minimize vertical numerical dispersion.

³⁰ The units represented by Layers 13, 14, and 15 were identified from the log of the USGS Hunter Ridge Park 1 Boring (Johnson and others, 1996).

6.1.1.1 Boundary Conditions

The eastern boundary of the model is a no-flow boundary located just east of the Rio Grande and oriented approximately parallel to the river. The northern and southern boundaries of the model are specified as no-flow boundaries along the eastern portion of these boundaries and as constant head boundaries along the western portion of these boundaries (see Figure 6.1). In the eastern portion of the model area, regional groundwater flow is away from the Rio Grande and approximately parallel to the northern and southern boundaries of the model and thus it is appropriate to specify these portions of the model boundaries as no-flow boundaries. In the western portion of the model area, however, regional groundwater pumping creates a divergence in groundwater flow directions. As a result, in the western portion of the model area the direction of regional groundwater flow is not parallel to the northern and southern model boundaries, and groundwater could flow in or out of the model boundaries; therefore, the western 5,000-foot portions of these boundaries were specified as constant-head boundaries to allow groundwater flow across these boundaries to be simulated (in or out of the model area). The western boundary of the model area is also simulated as a constant-head boundary.

The water levels on the constant head boundaries were estimated during model calibration. In the model calibration process the water-levels on the constant head boundaries were specified on the basis of five parameters. The five parameters were water levels in 1998 at the following locations: (1) in layer 1 at the eastern end of the constant-head segment of the northern boundary (4,959.47 ft MSL); (2) in layer 1 at the eastern end of the constant head segment of the southern boundary (4,950.63 ft MSL), (3) in layer 1 in the northwest corner of the model grid (4,954.37 ft MSL); (4) in layer 1 in the southwest corner of the model grid (4,948.04 ft MSL); and (5) in layer 1 in the center of the western model boundary (4,951.05 ft MSL). The locations of these constant-head boundary parameters are shown on Figure 6.1. Based on these five water levels, water levels were estimated at all constant-head boundary cells using the following algorithm:

1. Water levels along the constant-head boundaries in layer 1 in 1998 were calculated by linear interpolation from the 5 water levels described above. Water levels in subsequent years were calculated based on annual regional water-level declines that were derived based on an evaluation of long-term hydrographs of monitoring wells; an annual rate of decline of 0.4 foot was specified from 1998 through 2007 and an annual rate of decline of 2.0 feet was specified for 2008 through 2011. Examples of long-term hydrographs at three selected monitoring wells within the model domain are shown on Figure 6.3.
2. Water levels in constant-head boundary cells in layers 2 through 11 were calculated based on the water levels estimated in layer 1 and a specified vertical hydraulic gradient of 0.02 ft/ft. This vertical hydraulic gradient was assumed to be constant through time.
3. Water levels in constant head cells in layers 12 and 13 were calculated based on the water levels estimated in layer 11 and a specified water-level change across the 4800-foot clay of 2.34 feet. This water-level change was determined in the model calibration process.

4. Water levels in constant head cells in layers 14 and 15 were calculated based on water levels estimated in layer 13 and a specified water-level change of two feet across the clay unit represented by layer 14. The water-level change was estimated from water-level data from the USGS monitoring well cluster at Hunter Ridge adjacent to Arroyo de las Calabacillas.

6.1.1.2 Hydraulic Properties

Five hydrogeologic zones are specified within the model domain:

- Holocene-aged channel and flood plain deposits, also referred to as Recent Rio Grande deposits;
- the 4970-foot silt/clay unit, which represents Late-Pleistocene-aged overbank deposits;
- sands of the Upper Santa Fe Group, Late-Pleistocene-aged channel and flood plain deposits, and Late-Pleistocene-aged and Holocene-aged arroyo fan and terrace deposits, collectively referred to as the sand unit; and
- the 4800-foot clay unit;
- the 4705-foot clay unit.

The sand unit, which is primarily classified as USF2 facies assemblages 2 and 3 (Hawley, 1996), was subdivided into six subzones for purposes of model calibration:

1. Sand unit above the 4970-foot silt/clay unit, except near the far southeastern of the silt/clay unit, which represent Late-Pleistocene-aged arroyo fan and terrace deposits (this zone was defined north of the simulated discontinuity shown on Figure 6.1);
2. Sand unit above the 4970-foot silt/clay unit near the far southeastern extent of this unit (this zone was defined south of the simulated discontinuity shown on Figure 6.1);
3. Sand unit in the region between the western extent of the Rio Grande deposits and the eastern extent of the 4970-foot silt/clay unit (This zone is shown as the "Upper Sand Unit" on Figure 6.1);
4. Sand unit above the 4800-foot clay unit except above and in vicinity of 4970-foot silt/clay unit;
5. Sand unit between the 4800-foot clay unit and the 4705-foot clay unit (model layer 13);
6. Sand unit below the 4705-foot clay unit (model layer 15).

The spatial extent of the Recent Rio Grande deposits, the 4970-foot silt/clay unit, and the Upper Sand Unit are shown in Figure 6.1. Also shown on Figure 6.1 is the location of a discontinuity in the sand unit above the 4970-silt/clay unit. This discontinuity was simulated with the MODFLOW horizontal flow barrier package. The horizontal conductance of the barrier was specified as 10^{-6} per day.

The hydraulic conductivity, specific yield and specific storage in each of the hydrogeologic zones in the calibrated groundwater model are listed on the table below.

Hydrogeologic Zone		Hydraulic Conductivity, ft/d		Specific Yield	Specific ³¹ Storage, ft ⁻¹	Model Layers in which zone is present
		Horizontal	Vertical			
Recent Rio Grande deposits		150	0.025	0.2	2×10^{-6}	1-6
4970-foot silt/clay unit		0.0041	0.00003		2×10^{-6}	3
Sand unit	above 4970-foot silt/clay unit	40	0.2	0.2	2×10^{-6}	1
		99	0.5	0.2	2×10^{-6}	2
	above 4970-foot silt/clay unit near SE extent	40	0.3	0.2	2×10^{-6}	1,2
	between Recent Rio Grande deposits and eastern extent of 4970-foot silt/clay unit (Upper Sand Unit)	120	0.05	0.2	2×10^{-6}	1,2
	above the 4800-foot clay unit	25	0.2	0.2	2×10^{-6}	3-11
	in Layer 13	23	0.068		2×10^{-6}	13
	in Layer 15	22	0.1		2×10^{-6}	15
4800-foot clay unit		0.0042	0.00053		2×10^{-6}	12
4705-foot clay unit		0.2	0.058		2×10^{-6}	14

6.1.1.3 Sources and Sinks

The groundwater sinks in the model domain are the off-site containment well CW-1, the source containment well CW-2, and eight on-site shallow wells (PW-1, MW-18, and MW-23 through MW-28) that were extraction wells for an IM that was implemented in 1988. The off-site containment well has been in operation since December 31, 1998 with a brief shut down in April 1999. The pumping capacity of CW-1 was 225 gpm prior to November 3, 2010 at which time the pumping capacity was increased to 300 gpm. The average annual pumping rate is less than the pumping capacity due to downtime related to system maintenance. The average annual pumping rate has varied between 213 gpm and 225 gpm. The average pumping rate in 2010 was 218 gpm (207 gpm prior to November 2nd and 274 gpm after November 3rd). The pumping at CW-1 is distributed across model layers 6 through 11 and is apportioned based on layer transmissivities.³² The discharge from well CW-1 to the infiltration gallery is simulated using wells injecting into layer 2. The discharge is distributed across the area of the gallery and is specified at the same rate as the CW-1 pumping rate.

³¹ The specific storage of all model units was specified at 2×10^{-6} ft⁻¹ consistent with the value specified in the USGS model of the Albuquerque Basin (Kernodle, 1998). This value was not estimated during model calibration.

³² The production wells CW-1 and CW-2 are simulated in MODFLOW with the Multi-Node Well (MNW) package which dynamically allocates production to model layers based on water levels, hydraulic conductivity and layer thickness.

The source containment well, CW-2, began operation in January 2002. The well has operated at an average annual pumping rate of between 42 gpm and 52 gpm. The average pumping rate in 2010 was 42 gpm. The pumping at CW-2 is distributed across model layers 3 through 8.³ Ninety-nine percent of the treated water from this well is assumed to infiltrate back to the aquifer from the six on-site infiltration ponds based on consumptive use calculations. Only some of the ponds are used for infiltration at any given time; during 2002 the treated discharge from the well was rotated among the six original ponds, in 2003 and 2004 only ponds 1 and 4 were used, and from 2004 to 2010 the discharge was rotated among ponds 1 through 4 (see Figure 2.10 for pond locations). Ponds 5 and 6 were backfilled during 2005. In the model, the amount of water directed to each of the ponds was based upon operation records.

The shallow extraction wells were operated from December 1988 to November 1999. Total extraction rates from the wells declined with time. The average pump rate was 0.24 gpm in 1999. Since discharge from the shallow extraction wells was to the city sewer, infiltration of this water was not simulated in the model. Infiltration of precipitation is considered to be negligible due to high evapotranspiration and low precipitation.

Recharge within the modeled area is specified to occur from the Rio Grande and the Arroyo de las Calabacillas. Infiltration from the Rio Grande was simulated with the MODFLOW river package. The water level in the Rio Grande was estimated from the USGS 7.5 minute topographic map for the Los Griegos, New Mexico quadrangle and the river-bed conductance was determined as part of the model calibration process. Recharge along the Arroyo de las Calabacillas was simulated with the MODFLOW recharge package. This recharge rate was determined during the model calibration process to be 0.2 ft/year.

6.1.2 Model Simulated Water Levels from 1999 through 2010

The groundwater model was used to simulate groundwater levels in the aquifer system underlying the former Sparton site and its vicinity from December 1998, just prior to the startup of containment well CW-1, until December 2010 for purposes of evaluating correspondence between model calculated and observed water levels. An initial steady-state stress period was used to simulate conditions prior to startup, and this was followed by a month-long stress period for December 1998, and annual stress periods for the years 1999 through 2010. The average annual pumping rates specified for the containment wells CW-1 and CW-2 are those specified on Table 5.2.

A total of 843 water-level targets were used to evaluate the correspondence between model calculated and observed water levels. These targets were developed from average annual water levels for each year from 1998 to 2010 calculated from available water-level data for seventy-seven monitoring wells at the Sparton site and four piezometers maintained by the USGS at the Hunters Ridge site located near the infiltration basin on the north side of the Arroyo de las Calabacillas.

The calculated water levels in December 2010 with the calibrated groundwater model for the water table (UFZ), ULFZ, and LLFZ³³ are shown in Figures 6.4, 6.5, and 6.6, respectively. These calculated water levels are similar to observed water levels. The correspondence between observed and model-calculated water levels was evaluated using both qualitative and quantitative measures. The qualitative measures included: (1) the preparation of scatter plots of observed versus calculated water levels to provide a visual comparison of the fit of model to the observed water level data; (2) plots of observed and calculated water levels for the period 1998 through 2010 for each of the monitoring wells and piezometers used for model calibration; (3) maps of the difference between observed and calculated water levels for each of the major aquifer units; and (4) evaluation of model water balance.

Scatter plots of observed water levels versus calculated water levels between 1998 and 2010 for all monitoring wells in the UFZ above the 4970-foot silt/clay unit (on-site UFZ wells), for all wells in the UFZ, ULFZ and LLFZ except for those above the 4970-foot silt/clay unit, and for all wells in the DFZ are shown on Figure 6.7. In a model with good correspondence between calculated and observed water levels, the points on the scatter plot are random and closely distributed about the straight line that represents an exact match between the calculated and observed groundwater levels. The scatter plots shown in Figure 6.7 plot the average observed water level in each monitoring well during each year of the simulation against the average water level calculated for each well during each year of the simulation.³⁴ These scatter plots visually illustrate the excellent comparison between model calculated water levels and observed water levels in the UFZ/ULFZ/LLFZ and DFZ zones. In the on-site UFZ the correspondence between observed and calculated water levels is not as good as in the other zones. This is the result of significant heterogeneity in the sands above the 4970-foot silt/clay unit.

Plots of observed versus calculated water levels at all monitoring wells and piezometers used are shown in Appendix D on Figures D-1, D-2, and D-3. These plots indicate that the water-level trends in the observed and calculated water levels are very similar at almost all monitoring wells illustrating the close correspondence between observed and calculated water levels. The areal distribution of residuals in the on-site UFZ, the UFZ/ULFZ/LLFZ and the DFZ in 2010 are shown in Appendix D on Figures D-4, D-5 and D-6, respectively. An evaluation of these figures indicates that the spatial distribution of residuals is relatively random.

The model water balance was compiled for 1998, 2001, and 2010 to evaluate the reasonableness of groundwater flows within the model domain. The water balance consists of water inflows into the model domain, groundwater outflow from the model domain, and changes in groundwater storage within the model area. Water inflows consist of leakage from the Rio Grande, recharge along the Arroyo de las Calabacillas, on-site infiltration ponds and the infiltration gallery. Groundwater outflows consist of groundwater pumping from containment

³³ The ULFZ water levels shown on Figure 6.5 are based on model calculated water levels in model Layer 5 and the LLFZ water levels shown on Figure 6.6 are based on model calculated water levels in model Layer 9.

³⁴ Observed water levels were compared to calculated water levels in the model layer corresponding to the location of the screened interval of the monitoring well. When the screened interval of a monitoring well spanned more than one model layer, the observed water levels were compared to the transmissivity weighted average of the calculated water levels in the layers penetrated by the well.

wells CW-1 and CW-2 and groundwater flow out of the model domain across the constant-head boundaries. The water balance summaries for 1998, 2001 and 2010 in terms of gallons per minute (gpm) on an average annual basis are listed below³⁵:

	Component	1998 (gpm)	2001 (gpm)	2010 (gpm)
Inflows	Storage (net)	0	80	345
	Infiltration Gallery and Ponds	0	216	260
	River	1,180	1,224	1,422
	Recharge	7	7	7
	Total Inflows	1,187	1,526	2,034
Outflows	Containment Wells	0	216	260
	Constant Head (net)	1,187	1,314	1,774
	Total Outflows	1,187	1,530	2,035

The balance between total water inflows and outflows from the model area has a maximum error of less than 0.3 percent and is judged to be reasonable. The increases through time in inflows from storage and the river and outflows from constant heads are the result of increasing regional pumping.

The quantitative evaluation of the model simulation consisted of examining the difference between the 843 average annual water levels observed in the monitoring wells and piezometers at the former Sparton site and its vicinity and the corresponding calculated water levels for these monitoring wells. The difference between an observed and a measured water level is called a residual. Three statistics were calculated for the residuals to quantitatively describe the model calibration: the mean of the residuals, the mean of the absolute value of the residuals, and the root mean-squared error.³⁶ The mean of all the residuals is -0.25 ft, the mean of the absolute value of the residuals is 1.07 ft, and the root mean-squared error is 1.5. The minimum residual is -8.55 ft and the maximum residual is 5.99 ft, both for on-site monitoring wells. The absolute mean residual of 1.07 ft is considered acceptable since the observed water-level measurements applied as calibration targets have a total range of about 55.3 ft, and seasonal fluctuations of water levels are on the order of several feet. The quantitative statistics based on the monitoring wells in the major flow zones are listed below:

³⁵ The calculated inflows and outflows in 1998 and 2001 are slightly different than those reported in the 2009 Annual Report. These differences are the result of using a new version of MODFLOW that handles dry cells more efficiently (Bedekar and others 2011).

³⁶ The root mean-squared error is defined as $RMSE = \left[\frac{1}{N} \sum_{i=1}^N R_i^2 \right]^{1/2}$ where N is the number of calibration targets, and R is the residual. The root mean-squared error is close to the standard deviation when the mean error is small and the number of targets is large.

Flow Zone	Count	Mean Residuals	Absolute Mean Residual	Root-Mean-Squared Error	Minimum Residual	Maximum Residual
On-Site UFZ	194	0.20	1.63	2.15	-8.56	5.99
UFZ/ULFZ/LLFZ	608	-0.44	0.92	1.22	-4.38	3.94
DFZ	41	0.37	0.61	0.93	-0.85	3.50

The differences between observed and calculated water levels at each monitoring well for the period 1998 through 2010 are presented in Appendix D, Tables D-1 through D-3. The qualitative and quantitative evaluations of the comparisons between observed and model calculated water levels indicate that the groundwater model is a reliable simulator of existing conditions.

6.1.3 Capture Zone Analysis

The capture zones of containment wells CW-1 and CW-2 at the water table (UFZ) , and in the ULFZ and LLFZ were calculated by applying particle tracking to the calculated average 2010 water levels in these horizons of the aquifer (Figures 6.4, 6.5, and 6.6), assuming that these water levels represented a steady-state condition. The particle tracking was carried out using the PATH3D computer code (Zheng, 1991), and by releasing particles at one-foot intervals along a line upgradient from both containment wells, and near and parallel to Rio Grande (along column 129 of the model grid shown in Figure 6.1). The calculated capture zones of containment wells CW-1 and CW-2 in the UFZ (water table), the ULFZ, and the LLFZ are presented in Figures 6.4, 6.5, and 6.6, respectively. Also shown in these figures is the extent of the TCE plume in November 2010.

Particle tracking analysis was also used to determine the aquifer area where the water extracted at CW-1 between 1999 and 2010 was located at the start of extraction in 1998 and where the water extracted at CW-2 between 2002 and 2010 was located at the start of extraction in January 2002 (the “areas of origin”). This particle tracking analysis was carried out using the MODPATH computer code (Pollock 1994, 2008); particles were released on a twenty foot grid at the top of each model layer throughout the model domain, and keeping track of those particles that discharged at CW-1 and CW-2. The results of this analysis are discussed in Section 5 and are shown on Figure 5.29 in both map [Figure 5.29 (a)] and cross-section view [Figure 5.29 (b)]. The outlines of the areas of origin of the water pumped during different time periods [Figure 5.29 (a)] represent the outer boundary of the envelope of particle traces that discharged at each of the wells during that period.

The travel time from the center of the Sparton property (a point near monitoring well MW-26) to the source containment well CW-2, and the travel time from a point downgradient from and outside the capture zone of CW-2 to the off-site containment well CW-1 were estimated using the particle-tracking method. These travel times were calculated as 1.5 and 14

years, respectively.³⁷ This calculation assumed that both the off-site and the source containment wells are operating continuously at their current pumping rates (300 gpm at CW-1 and 47 gpm at CW-2) and that 2010 water level conditions exist throughout the 15-year period.

6.2 Solute Transport Model

A solute transport model is linked to the groundwater flow model to simulate the concentration of TCE in groundwater at the site. The three-dimensional contaminant transport simulation code MT3D (Zheng, 2008; Zheng and SSP&A, 1999) was applied for this study. The model was used to simulate TCE concentrations in the aquifer from December 1998 through December 2011.

Model input parameters were specified based on available data. The TCE concentrations in the model domain at the start of the simulation period were estimated from November 1998 measured concentration data. The model was used only to predict TCE concentrations in the aquifer and no attempt was made to simulate DCE and TCA. Generally, DCE is detected at monitoring wells where TCE is detected, but DCE concentrations are much lower than TCE concentrations. During 2010, DCE was about 8.5 percent of the total mass of chlorinated volatile organic compounds extracted by CW-1 and 12 percent of that extracted by CW-2.

The other constituent of concern, TCA, had been historically detected at concentrations greater than the 60 µg/L maximum allowable concentration in groundwater set by the NMWQCC, primarily in monitoring wells at the facility; prior to 2003 TCA had been detected at levels above 60 µg/L in only one off-site well, MW-46. The concentrations of TCA have been below 60 µg/L since 2003; the maximum TCA concentration reported this year was 4.7 µg/L at MW-60. The limited distribution of TCA and the reduction in its concentrations are the result of the abiotic transformation of TCA to acetic acid and DCE; a transformation that occurs relatively rapidly when TCA is dissolved in water. Only about 20 percent of TCA degrades to DCE, the rest degrades to acetic acid (Vogel and McCarty, 1987). The current concentrations of TCA and DCE in monitoring wells at the facility indicate that it is not likely that DCE concentrations will increase significantly in the future as the result of TCA degradation.

6.2.1 Transport Parameters

A number of aquifer and chemical properties are required as input parameters for the contaminant transport simulation. The required aquifer properties are porosity, bulk density, and dispersivity. The required chemical property is the retardation coefficient, which is a function of the fraction organic carbon, the organic-carbon partition coefficient for the organic compound being simulated, and the effective diffusion coefficient. The following table summarizes the transport parameters:

³⁷ This travel time is the travel time for ground water, and should not be construed as the time at which contaminants will migrate over the same distance; travel time for contaminants would be different due to dispersion and other factors that affect contaminant migration.

Transport Parameter	Geologic Unit	Value
Effective porosity	All	0.3
Longitudinal dispersivity	All	25 ft
Transverse horizontal dispersivity	All	0.25 ft
Transverse vertical dispersivity	All	0.025 ft
Retardation Coefficient	All except 4,970-foot silt/clay	1

The rationale for choosing these transport parameters is described in the 2000 Annual Report (SSP&A, 2001b). The retardation coefficient for TCE was specified as unity in all geologic units. In previous years, a retardation coefficient of 4.3 was specified for the 4970-foot silt/clay unit. In the model calibration conducted this year, it was determined that the model with a retardation coefficient of unity provided just as good a calibration as with a retardation coefficient of 4.3. Therefore, for simplicity a retardation coefficient of unity was specified.

6.2.2 Initial Concentration Distribution and Model Calibration

The transport model has been calibrated for each annual report since 1999, except for the 2006 annual report, by adjusting the TCE concentrations in the aquifer in 1998 prior to startup of the groundwater remediation systems; these concentrations are referred to as the model's initial concentration distribution. The calibration process consisted of adjusting the initial TCE concentration distribution in the aquifer in a manner consistent with available data until a reasonable match was obtained between the calculated and measured TCE concentrations, and the calculated and measured TCE mass removal at both containment wells, CW-1 and CW-2, throughout their respective period of operation. The previous recalibration of the transport model is described in the Alternatives Report. The initial TCE concentration distribution was adjusted slightly this year to provide a better representation of observed concentrations at CW-2.

The calibration procedure has varied through time. In the last recalibration, the initial concentration distribution was interpolated based on the November 1998 measured concentration data and a number of the pilot points along the center line of the plume using three-dimensional kriging. The parameter estimation program PEST (Doherty, 2002) was used to estimate TCE concentrations at the pilot points. Calibration procedures used in previous years are described in the 2006 Annual Report (SSP&A, 2007). The calibration process has resulted in good agreement between observed and calculated TCE mass removal from containment wells CW-1 and CW-2, and between observed and calculated concentrations at CW-1 and CW-2 (Figure 6.8).

The initial mass and the maximum TCE concentrations within each model layer, under the initial concentration distribution specified in the model based on the recalibration described in the Alternatives Report, are summarized on Table 6.1. The estimated initial mass of TCE is 7,360 kg (16,250 lbs). The estimate of initial mass has varied with each recalibration of the model as additional information has been learned from long-term operation of the containment wells, though the estimate of mass has not changed significantly since 2003. The estimates of initial mass presented in previous annual reports as estimated from model recalibration are listed below:

	Year											
	1999	2000	2001	2002	2003	2004	2005	2006	2007	2008	2009	2010
Estimated Initial Mass (kg)	2,180	3,100	3,300	4,650	7340	6,640	6,910	6910	6,880	6,600	7,360	7,360

6.2.3 Model Calculated TCE Mass Removal Rates and Concentration

The measured cumulative amount of TCE removed by operation of the on-site and off-site containment systems through the end of each year since 1999 and the model calculated amount of TCE removed are tabulated below:

Year	Cumulative TCE mass removed by both wells through end of year (kg)		Average Annual Concentration at CW-1 (µg/L)		Average Annual Concentration at CW-2 (µg/L)	
	Measured	Calculated	Measured	Calculated	Measured	Calculated
1999	360	480	829	1,107		
2000	820	970	1,055	1,131		
2001	1,340	1,470	1,205	1,160		
2002	1,940	2,020	1,225	1,099	723	691
2003	2,560	2,590	1,275	1,170	473	410
2004	3,160	3,170	1,317	1,280	301	268
2005	3,720	3,750	1,217	1,276	191	173
2006	4,230	4,270	1,166	1,190	153	123
2007	4,700	4,740	1,050	1,044	130	98
2008	5,130	5,150	982	908	90	85
2009	5,510	5,500	869	793	64	77
2010	5,820	5,810	703	698	52	73

There is excellent agreement between the observed and model calculated amount of TCE removed. The total TCE removed through the end of 2010 is about 5,820 kg; this amount is about 79 percent of the amount of TCE estimated to have been in the aquifer in 1998. The model calculated total TCE removal is also about 5,810 kg. Also listed on this table are the average annual measured and model calculated concentrations in the water pumped from CW-1 and CW-2 from 1999 through 2010.

A comparison of calculated to observed concentrations of TCE at all monitoring wells for all samples analyzed between November 1998 and November 2010 is presented in Figure 6.9. Also presented in Figure 6.9 is a comparison of calculated to observed concentrations of TCE for only those samples analyzed in November 2010 on which the individual data points are labeled with the well number. The general agreement between observed and computed concentrations is reasonable given the uncertainty of the initial contaminant distribution. Plots of calculated and observed TCE concentrations at selected monitoring wells during the period 1998 through 2010 are shown in Appendix D on Figure D-7. The calibrated initial TCE plume (November 1998), and model calculated TCE plumes for November 2001, 2005, 2008, and 2010 are presented in Figure 6.10; the concentration contours shown on this figure are based on the maximum TCE concentration simulated in any layer.

6.3 Simulation of TCE Concentrations in 2011

The groundwater model was used to forecast TCE concentrations in the aquifer and the mass extracted from CW-1 and CW-2 from January through December 2011. In this simulation the CW-1 pumping rate was specified as 300 gpm during 2011 and the pumping rate at CW-2 was specified at 47 gpm.

The calculated TCE concentrations in December 2011 are presented on Figure 6.11. The concentration contours shown on Figure 6.11 are based on the maximum TCE concentration simulated in any layer. The calculated TCE concentration in December 2011 at CW-1 is 487 $\mu\text{g/L}$. The calculated TCE concentration in CW-2 in December 2011 is 75 $\mu\text{g/L}$.

The calculated concentration at CW-2 in December 2011 is slightly higher than the average concentration observed in the well in 2010, which was 52 $\mu\text{g/L}$. This suggests the potential that the initial TCE concentrations specified in the 4970-foot silt/clay unit, which act as a long-term source of contamination to the underlying aquifer units, overestimate actual TCE concentrations in this unit. In future years, if the calculated TCE concentrations at CW-2 continue to overestimate observed concentrations, the initial TCE concentrations in the 4970-foot silt/clay unit will be further re-evaluated.

Section 7

Conclusions and Future Plans

7.1 Summary and Conclusions

Sparton's former Coors Road Plant is located at 9621 Coors Boulevard NW, Albuquerque, New Mexico. The Site is at an elevation of about 5,050 ft MSL; the land slopes towards the Rio Grande on the east and rises to elevations of 5,150-5,200 ft MSL within a short distance to the west of the Site. The upper 1,500 ft of the fill deposits underlying the Site consist primarily of sand and gravel with minor amounts of silt and clay. The water table beneath the Site is at an elevation of 4,975-4,985 ft MSL and slopes towards the northwest to an elevation of about 4,960 ft MSL within about one-half mile of the Site. At an elevation of about 4,800 ft MSL a 2- to 3-foot clay layer, referred to as the 4,800-foot clay unit, has been identified.

Investigations conducted at and around the Site in the 1980s revealed that soils beneath the Site and groundwater beneath and downgradient from the Site were contaminated. The primary contaminants were VOCs, specifically TCE, DCE, and TCA, and chromium. Remedial investigations that followed indicated that groundwater contamination was limited to the aquifer above the 4800-foot clay; current measures for groundwater remediation were, therefore, designed to address contamination within this depth interval.

Under the terms of a Consent Decree entered on March 3, 2000, Sparton agreed to implement a number of remedial measures. These remedial measures consisted of: (1) the installation and operation of an off-site containment system; (2) the installation and operation of a source containment system; and (3) the operation of an on-site, 400-cfm SVE system for an aggregate period of one year. The goals of these remedial measures are: (a) to control hydraulically the migration of the off-site plume; (b) to control hydraulically any potential source areas that may be continuing to contribute to groundwater contamination at the on-site area; (c) to reduce contaminant concentrations in vadose-zone soils in the on-site area and thereby reduce the likelihood that these soils remain a source of groundwater contamination; and (d) in the long-term, restore the groundwater to beneficial use.

The installation of the off-site containment system began in late 1998 and was completed in early May 1999. The system consisted of (1) a containment well near the leading edge of the plume, designed to pump at a rate of about 225 gpm, (2) an off-site treatment system, (3) an infiltration gallery in the Arroyo de las Calabacillas, and (4) associated conveyance and monitoring components. The off-site containment well began operating on December 31, 1998; except for brief interruptions for maintenance activities or due to power outages, the well has operated continuously since that date. Based on an evaluation of the performance of the system and of alternative groundwater extraction systems, conducted in 2009, Sparton recommended and the regulatory agencies approved the increase of the pumping rate of this well to about 300 gpm to accelerate aquifer restoration; this rate increase was implemented on November 3, 2010. The year 2010 was the twelfth full year of operation of this well.

The source containment system was installed during 2001 and began operating on January 3, 2002. This system consisted of: (1) a containment well immediately downgradient from the site, designed to pump at a rate of about 50 gpm, (2) an on-site treatment system, (3) six³⁸ on-site infiltration ponds, and (4) associated conveyance and monitoring components. The year 2010 was the ninth year of operation of this well.

The 400-cfm SVE system had operated for a total of about 372 days between April 10, 2000 and June 15, 2001 and thus met the length-of-operation requirements of the Consent Decree; monitoring conducted in the Fall of 2001 indicated that the system had also met its performance goals, and the system was dismantled in May 2002.

During 2010, considerable progress was made towards achieving the goals of the remedial measures:

- The off-site containment well continued to operate during the year at an average discharge rate of 207 gpm until November 3, 2010, and an average rate of 274 gpm during the remainder of the year. Hydraulic containment of the plume was maintained under both these average pumping rates. The pumped water was treated and returned to the aquifer through the infiltration gallery. The concentrations of constituents of concern in the treated water met all the requirements of the Discharge Permit for the site.
- The source containment well continued to operate during the year at an average rate of 42 gpm, and to contain potential on-site source areas. The pumped water was treated and returned to the aquifer through the infiltration ponds. The concentrations of constituents of concern in the treated water met all the requirements of the Discharge Permit for the site.
- To address agency concerns on the potential presence of contaminants beyond the capture zone of the off-site containment well, a new monitoring well, MW-80, was installed downgradient of the leading edge of the off-site plume and beyond the capture zone of the off-site containment well. No site-related contaminants were detected in groundwater samples from this well, and the well was placed on a quarterly water-level and water-quality sampling schedule.
- Groundwater monitoring was conducted as specified in the Groundwater Monitoring Program Plan [Monitoring Plan (Attachment A to the Consent Decree)] and the State of New Mexico Groundwater Discharge Permit DP-1184 (Discharge Permit). Water levels in all accessible wells and/or piezometers, and the Corrales Main Canal were measured quarterly. Samples were collected for water-quality analyses from monitoring wells at the frequency specified in the above plan and permit and analyzed for VOCs and total chromium.
- Samples were obtained from the influent and effluent of the treatment plants for the off-site and source containment systems, and the infiltration gallery and infiltration pond

³⁸ The performance of the six on-site infiltration ponds between 2002 and 2004 indicated that four ponds are more than adequate for handling the water pumped by the source containment well. With the approval of the regulatory agencies, Sparton backfilled two of the six ponds in 2005 to put the land to other beneficial use.

monitoring wells at the frequency specified in the Discharge Permit. All samples were analyzed for VOCs, total chromium, iron, and manganese.

- The groundwater flow and transport model that was developed in early 2000 to simulate the hydrogeologic system underlying the site and its vicinity, and which was revised several times during the past ten years was used to simulate TCE concentrations in the aquifer from start-up of the off-site containment well in December 1998 through December 2010, and to predict concentrations for December 2011. Minor adjustments were made to the model to improve its predictive capabilities in the source containment area.

The extent of groundwater contamination during 2010, as defined by the extent of the TCE plume, was essentially the same as during 2009. Of 56 wells sampled both in November 2009 and 2010, the 2010 concentrations of TCE were lower than in 2009 in 15 wells, higher in 17 wells, and remained the same in 24 wells (all below detection limits). Well MW-60, at 1,300 µg/L continued to be the most contaminated off-site well. The corresponding results for DCE were 11 wells with lower, 5 wells with higher, and 40 wells with the same (39 below detection limits) concentrations. The TCA plume ceased to exist in 2003, and this condition continued through 2010; the highest concentration of TCA during 2010 was 4.7 µg/L (also in well MW-60) significantly below the maximum allowable concentration of 60 µg/L set for groundwater by the NMWQCC.

Changes in concentrations observed in monitoring wells since the implementation of the current remedial measures indicate that contaminant concentrations in the on-site area decreased significantly. Concentrations in most off-site wells have also decreased, or remained unchanged (below detection limits). Of six wells where current concentrations are higher than they were prior to the start of the current remedial operations, the highest increase was at the off-site containment well CW-1. The concentrations of contaminants in the water pumped from CW-1 rapidly increased after the start of its operation and remained high for several years before starting a declining trend in 2005. The high concentrations in this well and in well MW-60 indicated that areas of high concentration existed upgradient from both of these wells; however, most of the groundwater upgradient from these wells has been captured by CW-1 and concentrations both in CW-1 and MW-60 are expected to continue their declining trend.

Two of the three DFZ monitoring wells, well MW-67 and well MW-79, which was installed in 2006 to address the continuing presence of contaminants in DFZ monitoring well MW-71R, continued to be free of any site-related contaminants throughout 2010. Well MW-71R continued to be contaminated; however, TCE concentrations in the well declined from 210 µg/L in August 2003 to 51 µg/L in May 2009; during 2010, the TCE concentrations in the well ranged from 54 µg/L in February to 67 µg/L in August; the November 2010 TCE concentration in the well was 64 µg/L. The absence of any contaminants in MW-67 and MW-79, and the declining concentrations in MW-71R indicate that the contamination in DFZ represents a contaminated groundwater slug of limited extent. Concentration trends in MW-71R will continue to be closely monitored in the next few years to assess if there is a need for further action.

The off-site and source containment wells operated at a combined average rate of 260 gpm during 2010. A total of about 137 million gallons of water were pumped from the wells. The total volume of water pumped since the beginning of the current remedial operations on December 1998 is about 1.61 billion gallons and represents 142 percent of the initial volume of contaminated groundwater (pore volume).

A total of about 340 kg (750 lbs) of contaminants consisting of about 3210 kg (680 lbs) of TCE, 29 kg (64 lbs) of DCE, and 1.0 kg (2.1 lbs) of TCA were removed from the aquifer by the two containment wells during 2010. The total mass that was removed since the beginning of the of the current remedial operations is 6,210 kg (13,710 lbs) consisting of 5,820 kg (12,820 lbs) of TCE, 376 kg (830 lbs) of DCE, and 17 kg (38 lbs) of TCA. This represents about 79 percent of the total dissolved contaminant mass currently estimated to have been present in the aquifer prior to the testing and operation of the off-site containment well.

The containment systems were shutdown several times during 2010 for routine maintenance activities, due to power and monitoring system failures, due to low levels in the chemical feed tanks, or due to the failure of other components of the systems. The downtime for these shutdowns ranged from 10 minutes to 195 hours; this latter shutdown of over 8 days was for replacing the pump at the off-site well and making other adjustments to the off-site system in preparation of increasing its pumping rate. Evaluation of migration rates in the aquifer indicates that the systems could be down for significantly much longer periods without affecting the capture of the contaminant plume.

7.2 Future Plans

The off-site and source containment systems will continue to operate during 2011; their pumping rates will be closely monitored to maintain them as close a possible to their design pumping rates (300 gpm for the off-site containment well and 50 gpm for the source containment well). The pipeline between the source containment well and the treatment plant will be cleaned in 2011 to restore the well's design pumping rate.³⁹ Data collection will continue in accordance with the Monitoring Plan and the Discharge Permit, and as necessary for the evaluation of the performance of the remedial systems. As additional data are collected, they will compared to predictions made with the calibrated flow and transport model of the Site, and adjustments to the model will be made, if necessary.

The plugging and abandonment of monitoring wells MW-13 and MW-48 and the deepening of well MW-57, which has been approved by the agencies, will be implemented during the summer of 2011. In addition, it is proposed that monitoring wells MW-58 and MW-61, which have been dry or did not have sufficient water for sampling during the last several years, be also plugged and abandoned. Well MW-58 is located between well MW-53D and MW-56, and these two wells would provide sufficient data for defining the ULFZ water levels and water quality in this area; well MW-61 is next to MW-60 which will continue to provide ULFZ data at this location. It is also proposed that well MW-47, which also did not have sufficient water for sampling during the last several years, be deepened to continue to

³⁹ This task was completed in mid-January 2011, and the pumping rate of the well was restored.

provide data for the shallow zones of the aquifer at this location. These proposed monitoring well modifications will be implemented upon approval of this 2010 Annual Report by USEPA and NMED. Also, after approval of the report, a Fact Sheet for 2010 will be prepared and submitted to the regulatory agencies for approval before distribution to the property owners located above the plume and adjacent to the off-site treatment plant water discharge pipeline.

Responsibility for data collection and other activities that were previously conducted by Metric has been taken over by SSP&A effective June 1, 2011. The USEPA and the NMED will continue to be kept informed of any significant milestones or changes in remedial system operations. The goal of the systems will continue to be the return of the contaminated groundwater to beneficial use.

^a UFZ denotes the Upper Flow Zone; ULFZ and LLFZ denote the upper, lower, and deeper intervals of the Lower Flow Zone (LFZ); DFZ denotes a deeper flow zone separated from the Lower Flow Zone by a continuous clay layer that causes significant head differences between LFZ and DFZ.

^b New Mexico "Modified State Plane" coordinates, in feet.

^c In feet above mean sea level (MSL).

^d Elevation effective February 1, 2005.

^e Elevation effective March 12, 2008.

^a The letter R after the number in the Well ID indicates that the well is a new and deeper replacement well installed near the original well location; the letter D after the number in the Well ID indicates that the well has been deepened.

Table 2.3
Production History of the Former On-Site
Groundwater Recovery System

Year	Volume of Recovered Water (gal)	Average Discharge Rate (gpm)
1988 ^a	25,689	1.05
1989	737,142	1.40
1990	659,469	1.25
1991	556,300	1.06
1992	440,424	0.84
1993	379,519	0.72
1994	370,954	0.71
1995	399,716	0.76
1996	306,688	0.58
1997	170,900	0.33
1998	232,347	0.44
1999 ^b	137,403	0.26
Total Recovered Volume (gal)	4,416,550	
Average Discharge Rate (gpm)		0.77

^a System began operating on December 15, 1988.

^b System operations were terminated on November 16, 1999.

^a Water levels were measured on November 10, 1998, except for wells PW-1, MW-18, and MW-23 through MW-28 which were measured on November 25, 1998.

^b UFZ O/S denotes UFZ wells, mostly on-site, which are screened above or within the 4970-foot silt/clay.

^a Includes February 18, 1998 data from temporary well TW-1/2 which was drilled at the current location of well MW-73, and September 1, 1998 data from the containment well CW-1 and observation wells OB-1 and OB-2.

Note: Shaded cells indicate concentrations that exceed MCLs based on the more stringent of the drinking water standards or the maximum allowable concentrations in groundwater set by the NMWQCC (5 mg/L for TCE and DCE, and 60 mg/L for TCA).

^a Well not sampled (NS) because it was dry or did not have sufficient water for sampling.

^b Results for well are the average of duplicate samples.

Note: Shaded cells indicate concentrations that exceed MCLs based on the more stringent of the drinking water standards or the maximum allowable concentrations in groundwater set by the NMWQCC (5 mg/L for TCE and DCE, and 60 mg/L for TCA)

Notes: NA = Not analyzed

Shaded cells indicate concentrations that exceed MCLs based on the more stringent of the drinking water standards or the maximum allowable concentrations in groundwater set by the NMWQCC (5 ug/L for TCE and DCE, 60 ug/L for TCA, and 50 ug/L for total chromium).

^a Data from January 3, 2011 has been included to show conditions at the end of the year.

Notes: Shaded cells indicate concentrations that exceed MCLs based on the more stringent of the drinking water standards or the maximum allowable concentrations in groundwater set by the NMWQCC (5 ug/L for TCE and DCE, 60 ug/L for TCA and 50 ug/L for total chromium).

^a Data from January 3, 2011 has been included to show conditions at the end of the year.

Notes: Shaded cells indicate concentrations that exceed MCLs based on the more stringent of the drinking water standards or the maximum allowable concentrations in groundwater set by the NMWQCC (5 ug/L for TCE and DCE, 60 ug/L for TCA and 50 ug/L for total chromium).
